A key element of Geertz's argument was to explore the constructed meanings of sainthood and Sufism (mysticism) in the two contrasting settings. In Morocco, individuals with highly varied attributes – reputations for piety, scholarship, miracle working, or other distinctions – were popularly imputed with saintly authority. Since the current Moroccan social order took hold in the fifteenth century, Geertz argued, the cultural order in which Moroccan ideas of saintly authority was sustained was characterized by a 'strong man' politics of zealous warriors, rulers, and saints enforcing their will and inducing clients to act on their behalf. Their authority was charismatic, based on personal dominance. In contrast, the Indonesian view of sainthood is hierarchical. Saints incrementally achieved prominence through years of meditation and Indonesia's settled agricultural villages placed high value on cooperation and order.

In the contexts of both Indonesia and Morocco, the idea of saintly authority took significantly divergent forms because of the contrasting nexus of commonsense perceptions of the world and the different historically constructed senses of meaning through which Indonesians and Moroccans interpreted Islam. These commonsense perceptions and background understandings form the necessary point of departure for understanding religious belief, experience, and practice. Indeed, the perspectives of religion and commonsense are

intertwined in a dynamic, often unstable, dialectic (Zein, 1977; Eickelman, 2005).

Theologians and 'common' people interpret religious texts, including the 'foundation' texts of religious traditions such as the Qur'an, in multiple and contested ways. Thus, the most common term for saint in contemporary Morocco is 'pious one' (*salih*), although 'marabout', the term used by Geertz and which has made its way into French and English usage, is also understood. 'Pious one' conveys the multivalence of Moroccan usage. For educated Moroccans, the term is reserved solely for individuals of outstanding piety, and many speak of saint, or maraboutic, cults as 'pre-Islamic' vestiges. For many other Moroccans, however, both in towns and in rural areas, the 'pious ones', living or dead, are imputed with mystical powers, including the ability to secure positive outcomes for individuals and groups who have maintained a connection with them through gifts or donations to their descendants (Eickelman, 1976). Moroccan monarchs and senior government officials continue publicly to visit the shrines of pious ones and make gifts toward their maintenance. Elsewhere in the Muslim world there is a similar interplay between different notions of piety, and there is a similar dialectic of ideas of sainthood among Jews of North African origin (Weingrod, 1990).

The emphasis Geertz placed on the cultural dimension in understanding religious experience suggested an alternative to characterizing religious traditions in terms of an essential core prevalent in all places and for all historical periods. His approach instead stresses how systems of religious meaning and practice, like all cultural experience, are contested and dynamic, and therefore not reduced to a single, cohesive set of principles. Some conceptions of Islam are significantly intertwined with, although not limited to, the local social order. However, other conceptions are more universalistic and global, amenable to articulation with a wide range of contexts. These universalistic and particularistic conceptions are copresent and in a dynamic, often volatile, tension with one another.

Geertz's approach, like other efforts to understand religious expression and practice in Moroccan society and elsewhere, including Ernest Gellner's *Muslim Society* (1981) – note the singular – had significant implications for understanding religious expression in earlier historical periods and outside the Muslim majority world. For example, Brown (1981) notes that his understanding of the moral order of early Latin Christianity, the 'lasting, urgent problems of any civilized community – friendship and protection, justice, power and mercy' – were in part inspired by ethnographies of contemporary North African saints. Similarly, Cornell (1998) shows how medieval Moroccan arguments on the nature of sainthood – cultural understanding of and debates among mystics in both urban and rural settings about concepts related to God's love and authority from the eleventh through sixteenth centuries – contributed to the Sufi tradition elsewhere in the Muslim world. Cornell's argument also compares the North African experience with sainthood as understood and practiced in Europe in the same period. Writings on Judaism in North African and Middle Eastern societies likewise indicate a reemphasis on the cultural dimension and explore the significance of local cultural contexts (Deshen, 1989; Goldberg, 1996; Gottreich and Schroeter, 2011).

The Iranian Revolution and Religious Politics

The 1978–79 Iranian revolution was one of several major events that underscored the continued significance of religion in politics and public life, notwithstanding its neglect in most midtwentieth century discussions concerning modernization and modernity. In Iran itself, the revolution led to the creation of a new, rapidly changing religious idiom for interpreting religious, social, and political events – and to contesting them (Khosrokhavar, 1997; Adelkhah, 2012). The debates in Iran continue unabated over the form that an Islamic state should take and the role that religion should play in society, including gender relations (e.g., Mir-Hosseini, 1999; Adelkhah, 2000). Successive incremental decisions and the unanticipated outcomes of earlier ones meant that the revolution looked different in the decades after the event both to many of those who participated in it and to the majority of Iranians not even born when it happened. Some observers use the term 'post-Islamism' to describe Iranian society in the 1990s, emphasizing the significantly different way that many Iranians, including many clerics, began to argue publicly for a more limited role of religious institutions in Iranian politics and public life (Khosrokhavar and Roy, 1999).

In spite of contemporaneous hopes for some and fears for others at the time of the Iranian revolution, it did not trigger similar political movements in other Muslim majority countries. It did, however, compel regimes elsewhere in the Middle East, both secular (including Egypt, Turkey, Syria, and Algeria) and religiously oriented (including Morocco and Saudi Arabia) to become more attentive to popular understandings of social justice and religion in society. From the first decades of the twentieth century, new religious movements emerged that had distinctly modern political forms. Egypt's Muslim Brotherhood, founded in the late 1920s and regarded by the midtwentieth century as Egypt's only genuinely popular mass political movement, foreshadowed the growth of similar later Islamic movements, many of which benefit from their ability to attract leaders with strong skills in organization and communication. Distinctly modern in organizational form, with a clear hierarchy and (at least at the outset) formal criteria for membership, the Brotherhood's leadership rested not with traditionally educated religious scholars but with those effective in organizing their followers and articulating their values, providing social and medical services as well as religious inspiration in many communities. After the fall of the Mubarak regime in Egypt in February 2011, Egypt's Muslim Brotherhood reemerged as a powerful political force, but with strong competition from other secular and religious groups. As after many changes in political authority, those kept by force from exercising political authority and rights in Egypt and elsewhere in the region show inexperience in managing the state machinery once in office. The result has been to engender significant competition from both religious groups, whether or not formally organized for political purposes, and secular ones.

As dramatic as the events of the 2011 'Arab Spring' were in some parts of the Middle East, they were in many ways the culmination of long-term shifts in economy, society, and religious expression and practice. As early as the 1960s, for example, the Muslim Brotherhood and similar organizations looked conservative in contrast to the proliferation of

movements advocating the Islamization of politics and society. These 'Islamist' movements ranged from small, radical groups such as the one responsible for the assassination of Egypt's Anwar Sadat in 1981 to larger ones sometimes organized like political parties, such as Hizbullah of Lebanon, the Virtue Party of Turkey (succeeded in 2001 by the Justice and Development Party (AKP)), or the Islamic Salvation Front of Algeria. Some of these Islamist movements had their origins as 'spokesmen for the despised', and had Jewish and Christian analogues (Appleby, 1997; Marty and Appleby, 1995). In general, the influence of extremists, having taken off in the late 1960s, appeared to have waned by the 1990s (Kepel, 2000), only to have subsequently regained momentum. Most movements work within existing national boundaries, even if they sometimes receive external or transnational support. Some movements have advocated violence to achieve their goals, but others have been strong advocates of tolerance and civil society, and many movements have altered as they enter the mainstream of national political life.

Religion as System and Ideology

Since the latter half of the twentieth century, mass education and the proliferation of new communications media have profoundly altered how religious knowledge and practice are produced and understood in the Middle East. In the Arab world, for example, large numbers of people now have the level of literacy needed to follow religious and political debates from multiple sources and the command of formal language needed to participate effectively in public life. The religious lessons learned from state schooling may be regarded with skepticism, but like other aspects of state schooling, they inculcate the habits of thought and language needed to learn about and elaborate alternative views of the role of religion in society.

Ironically, the ideas of many radical Islamists mirror competing secular ideologies in form and structure. The writings of Sayyid Qutb, executed by Nasser's Egypt in 1966, attracted a wide audience among white-collar workers, professionals, and students, the beneficiaries of modern education. In Arabic and in translation, Qutb's writings continue to have widespread appeal because they offer 'Islamic' explanations for contemporary political and economic developments and for the perceived injustices of existing regimes. More contemporary religious ideologues, like Morocco's 'Abd al-Salam Yasin (1928–2012), argue that contemporary Muslim societies have been de-Islamized by imported ideologies and values. Yet the style and content of these writers, like others, imply an audience already familiar with the secular, imported ideologies against which they argue. This is the case even for the writings and speeches of Osama bin Laden (1957–2011) (Euben and Zaman, 2009). Implicitly, they also convey a sense of Islam as an ideology and objectified system of meaning, which can be conveyed as one subject among others in schools, and in catechism-like pamphlets. In this sense, religion forms one of several systems of meaning in modern society, even as some believers argue that Islam is a 'complete' way of life. Yet the argument of 'completion' does not mean closure. As Iqtidar (2011) argues in a key study on a leading Islamic group in Pakistan that has moderated its views and practices as it becomes more mainstream, the contents of *shari'a* and 'tradition' are constantly contested and adapted to changing social and economic circumstances.

The awareness of alternatives to immediate social circumstances is facilitated by the increased availability of contemporary forms of communication, ranging from the press and broadcast media to readily duplicated DVD (which have largely replaced audio cassettes), ubiquitous mobile telephones, and the Internet. In an earlier era, state authorities easily regulated the media. By the end of the twentieth century, the top-down asymmetry of broadcast radio and television was reversed by newer media that are readily adaptive, interactive, and difficult for states effectively to control. These developments have contributed to the fragmentation of religious and political authority by allowing large numbers of people to participate in an increasingly public debate over the symbolic language of Islam (Eickelman and Anderson, 2003). Combined with political change and the growth of diaspora communities, these developments indicate a changed social and cultural environment for religious expression and practice in which a mass and anonymous public has given way to one characterized by an increased multiplicity of horizontal relationships. The shift to a network society has created communities and communicative spaces in which large numbers of people, while not abandoning their ties of family and community, discover and create alternative ways of thinking about the role of the sacred in society and politics.

Abstract

This article explores how the study of Middle Eastern society and history has moved gradually from a focus on homogeneity and continuity to more elaborate discussions of the impact of many determining factors. It is now commonly accepted that due to its historical centrality to historical world systems and its contemporary geopolitical significance, Middle Eastern society and history cannot be understood apart from global trends which influence the region and are influenced by it as well. The studies are most revealing when they go above or below contemporary state jurisdictions and emphasize instead the historically autonomous mode of self-organization of civil society, cultural communities, travel, and trade. Middle Eastern society has historically been defined more so by the hybridity and diversity resulting from the above factors than by the social engineering of states.

Study of the 'Middle East'

The term 'Middle East' first came into use in the early twentieth century, and after World War II it gradually supplanted the nineteenth century term 'Near East' as a geopolitical and geocultural designation. Both terms have been repeatedly criticized for their Eurocentric origin and point of emphasis, yet the term 'Middle East' continues to survive as a term for lack of better alternatives. It supplanted older designations such as the Levant, which designated the eastern Mediterranean and included present-day Turkey and Greece. Geographically, the Middle East encompasses West Asia, including Iran and Turkey, and North Africa, including Sudan. Some scholarly journals extend its boundaries further to include Afghanistan and the Horn of Africa. While in modern history the region has been divided among more than two dozen States, many historians and social scientists assume its various parts to contain roughly homogenous cultural patterns and sociological profiles, shaped by a shared history. Middle Eastern culture is frequently discussed in religious rubrics, and religiosity (specifically Islamic) and is frequently thought to capture what is essential about Middle Eastern culture in general. An earlier tradition in Western social science regarded Middle Eastern society culturally as tradition bound and sociologically as a tribally identified and ethnically segmented premodern mosaic kept together normally by an authoritarian State.

The social scientific study of the region we now call the Middle East is quite old, although its history is uneven. Ibn Khaldun (1332–1406), who spent most of his life in North Africa, was the first person to use the term 'sociology,' which he understood as the science of the life cycles of urban civilization. His theories, which emphasized the role of social solidarity and the weakening of that solidarity over time as civilization became more entrenched and oriented toward surplus and luxury, anticipated by centuries of European theories of civilizational cycles, expressed most loudly by Arnold Toynbee and Oswald Spengler. Ibn Khaldun's work must also be understood in the context of his time, which was characterized by conflicting claims of legitimacy, unstable political orders, recurrent Mongol invasions, the political fragmentation of the Muslim world, and the demonstrated incapacity of sovereigns to claim monopoly over the loyalties of the faithful everywhere, as had been roughly the case in the first three centuries of Islam.

An important feature of Ibn Khaldun's perspective consisted of combining the study of society and history, in the underlying belief that a sociology of civilization could only be based on an adequate philosophy of history. This continues to be the spirit characterizing much of the sociological investigation done in the Middle East itself, where many practitioners are just as likely to be historians or philosophers, and where questions of culture, religion, heritage, and modernity are inseparable from a myriad of contemporary social issues.

The modern professional study of the Middle East began in the nineteenth century from two directions. In the East, there arose an intellectual movement which came to be known as the *nahda*, whose significance has been pointed out in a recent flow of important studies by Albert Hourani, Hisham Sharabi, Aziz Al-Azmeh, and Sadiq Jalal al-'Azm, among many others. That movement was essentially an eclectic mix of reflexive native commentators whose thought was in tune with urban middle-class sentiments and in communication with European modernity. They sought to revive what they regarded to be a dormant spirit of science and liberalism in Islam, while seeking politically to modernize the Ottoman State. In Europe, by contrast, the study of the Middle East was far more scholastic and was confined to a small circle of orientalist scholars who, in the course of the nineteenth century, became increasingly better acquainted with the classic texts and archaeology of the region, especially following Napoleon's Egyptian campaign. The orientalist approach was highly antisociological and antitheoretical. It focused almost exclusively on ancient history and disregarded contemporary society, which was thought to be largely static in terms of its cultural patterns, and thus accessible through knowledge of the classic texts founding it. Influential trends within orientalism viewed oriental society culturally as static, antirational, unphilosophical, and antiscientific; sociologically as mosaic of floating tribal and ethnic solidarities; and politically as predisposed to authoritarianism.

This approach gained further ascendance within sociology itself with Max Weber's ventures into the study of oriental

cultures, including Islam. In common with the reigning orientalist tradition, Weber's approach to the question as to why Muslim societies (along with Buddhist and Hindu ones) had not developed capitalism as Europe had done, referred to the Qur'an and sayings attributed to Muhammad, and assumed the cause of social change (or lack of it) to be internal rather than external to the culture. While Weber was more interested in social theory than were orientalist scholars, who were preoccupied with philological and textual concerns, Weber nonetheless replicated the basic image of oriental society as a self-enclosed and distinct cultural cocoon, interpretable by its classical texts and definable in terms of its difference from the European experience of liberal capitalism.

The subsequent rise of modernization theory, closely associated with the Parsonian paradigm in sociology, set aside for some time the question of culture, emphasizing instead on the normative convergence of societies along the path of modernization. Daniel Lerner's *The Passing of Traditional Society* (1958) is a classic work in this genre with respect to the Middle East. While steeped in orientalist assumptions that Middle Eastern society, culture, and personality were largely tradition-bound and antirational, Lerner's work sought to detect venues of the modernist challenge arriving to society from without. Like many theorists of modernization, Lerner understood it as simply 'Westernization.' Another important text of modernization theory was C.A.O. van Nieuwenhuijze's *The Sociology of the Middle East* (1971), a detailed and lengthy study which portrayed Middle Eastern society as a set of parallel societies converging upon a cultural core. This further justified the old view of culture as an independent variable when approaching Middle Eastern societies.

Contemporary Approaches to Near Eastern/North African Societies

With decolonization, the increased presence of the United States in the region, the Cold War, the creation of the State of Israel, the rise of Arab nationalism, and the Arab defeat in 1967, Middle East studies itself became a veritable battleground. A new generation of scholars was determined to contest what they regarded to be a distorted image of the region and its peoples in both academic and public settings. The rallying cry was issued by Edward Said's *Orientalism* (1978), which immediately galvanized the field and continues to be referenced today as a founding text in postcolonial studies, generally. A sophisticated critical appraisal of the academic and high culture representations of largely Middle Eastern societies, *Orientalism* was conceived by Said as part of a trilogy, which included two subsequent books on the media coverage of Islam and the Palestine question. Said sought to reveal classical orientalism, which modernization theory did little to contest, as the intellectual regurgitation of common stereotypes based less on social and historical realities than on the tendency of European intellectuals to imagine a distinction between Europe and the rest of the world.

While Said's analysis was directed largely at mainstream trends in Western scholarship of the Middle East, another set of scholars set out around the same time to contest the heritage of orientalism in left-leaning scholarship. The main point of contention here was Karl Marx's thesis of an 'Asiatic mode of production,' distinct from European feudalism in its propensity to stagnate after a founding phase, needing a strong central State for its maintenance, and incapable of producing mercantile surplus that could found a basis for capitalism. While his method was fundamentally different from Weber's, Marx nonetheless reached the same conclusion regarding the foreignness of capitalism to the orient in general, and thus positing the need for an external stimulus, such as European colonialism, to introduce the bases of bourgeois accumulation and, in turn, the precondition of proletarian socialism. In spite of the brevity and inconclusive nature of Marx's own remarks on this theme, which addressed sporadically the encounter between India and Algeria with European colonialism, his assessment of the lack of internal capacity of oriental societies for capitalism and thus revolution has reigned well into our times. For example, Shlomo Avineri, a Marxist Israeli political theorist, has argued that Israel, by introducing into 'traditional' Middle Eastern society the same forces of destruction of 'Asiatic' patterns, would also add a revolutionary stimulus to the sum total of productive forces in the region.

This line of thinking was contested in a number of widely-referenced works from the recent past. They include Maxime Rodinson's *Islam and Capitalism* (1973), which took both Weber and Marx to task for failing to appreciate the paramount role of the urban merchant class throughout the economic history of the Middle East, for their propensity for partial appraisal of Islamic economic doctrines, for their tendency to confuse religion and culture, and for treating Islam, in particular, as a monolithic force. Rodinson argued that the Muslim world in general had a historically strong merchant capitalist class, and that, if anything, Islam was more of an aid than an obstacle to its interests. Mahmood Ibrahim took the argument further, arguing in *Merchant Capital and Islam* (1990) that the rise of Islam itself must be understood in terms of its connection to the interests of merchant capital and long-distance trade. The argument was also made in Janet Abu-Lughod's *Before European Hegemony* (1989) where, using a world-system perspective, she shows both the centrality of the Middle East to premodern world systems and the evolution of common modes of capitalist thinking and planning among commercial classes throughout the world well before the rise of the West.

The academic attacks on the leftist variety of orientalism were sealed in a number of other works which sought to demonstrate the capitalist vitality of Middle Eastern societies in early modern times. These include Peter Gran's *Islamic Roots of Capitalism: Egypt, 1760–1840* (1979) and Surayah Faroqhi's *Towns and Townsmen of Ottoman Anatolia* (1984). In *Marx and the End of Orientalism* (1978), Bryan Turner attempts to revalidate Marxist analysis and the mode-of-production approach to Middle East studies by repudiating the Asiatic mode of production thesis altogether and presenting a more tenable historical and theoretical alternative. An overarching treatment of the subject matter from a much broader perspective is Halil Inalcik's *Economic and Social History of the Ottoman Empire: 1300–1914* (1994).

Those studies also occasion the beginning of the application of a political economy framework to the study of Middle Eastern history and society. In his pioneering *The Middle East in World Economy: 1800–1914* (1981) and subsequent works,

Roger Owen identifies major global economic factors at work in the final century of Ottoman domination, factors which reshuffled the social structure within the region. Owen argues that Europe's increased demand for agricultural commodities during that period strengthened coastal parts of the Middle East at the expense of internal ones, and produced small local elites tied to European commerce. Those elites failed, nonetheless, to invest back in agriculture and industry, thus causing a development in the direction of dependency rather than modern, locally rooted capitalism. Owen's thesis marks an avowed application of dependency theory, hitherto common in Latin American studies, to Middle Eastern studies. A similar approach which situates the history of Iran, omitted from his analysis by Owen, in the context of the world system is John Foran's *Fragile Resistance* (1993). Other political economists such as Yusif Sayigh (1979), Abbas Alnasrawi, and Jacqueline Ismail do the same for other parts of the region.

Some works in this genre stand out because they attempt to connect political economic analysis to historical formations in the culture at large. In *The Arab Nation* (1978), Samir Amin outlines the basis of a pan-Arab nation in a historical, far-flung urban network maintained by a commercial warrior class that generated the surplus upon which it depended from long-distance trade rather than from the adjoining peasantry, which remained unincorporated. This feature meant that the fate of the Arab nation would always be dependent on factors external to it, and thus explained why the Arab nation readily entered the modern era in the logic described by dependency theory.

Of particular concern in studies of the political economy of the Middle East is the question of the nature and the role of the State. The fact that for much of its history the Middle East was governed by loose, territorially expansive States rather than confined city-states meant that local civil society, social networks, and even identities could exist and evolve at a distance from State doctrines. The historian Roy Mottahedeh, for example, has shown how medieval Muslim society in Buyid Iran could function without the trappings of the State as such. While in general the term 'nation-state' would not adequately describe Middle Eastern polities, there were notable attempted exceptions. These involved projects aiming at building nation-states along the European model, as in nineteenth century Egypt and Kemalist Turkey following the dissolution of the Ottoman Empire in the aftermath of World War I. The State that Mehmed Ali set out to build in Egypt in the early nineteenth century paralleled the European State in its extension of the range of its social roles, its curtailment of clerical prerogatives, the strengthening of direct state presence in the countryside, its reliance on regular levies and taxes, and the introduction of educational and health reforms. As in Europe, that kind of State began to assume for itself many functions that had historically been within the domain of civil society.

But such state experiences tended to be the exceptions, and even the Egyptian State was unable to demonstrate credibly its sovereignty in the face of colonialism. On the other extreme of experiences of state formation is the Persian Gulf region, whose political history until modern times had known only ephemeral States at best. In *State and Society in the Gulf and the Arab Peninsula* (1990) Khaldoun H. Al-Naqeeb identified the pre-eighteenth century political economy of the Gulf as a 'natural economy,' because all its components, including long-distance trade across the Indian Ocean, lacked the services and supervision of a centralizing state apparatus. Al-Naqeeb's thesis was that such a natural economy was eventually destroyed by British imperialism, which supported the rise of new dynasties and authoritarian, rentier States. Such States thus had to be run (until today) as official or unofficial protectorates.

This reality, coupled with the newness of all Arab States in the Levant and North Africa, has led some commentators like Michael Hudson in *Arab Politics: The Search for Legitimacy* (1977) to identify the question of legitimacy as the central problem of postcolonial polities in the region. This stance essentially dismisses the relevance of much of the common practice in political science writing about the region, which generally takes States as normative categories of analysis, focuses attention on diplomatic history and games theory, and pays little attention to ideologies, social movements, political parties and organizations, and also to such questions as political alienation and, above all, legitimacy.

New directions of research thus began in the early twenty-first century to address more complicated issues regarding the nature of the State in the region. At least three directions of research can be identified in this connection. One involves projects oriented toward studying the historical sociology of the State in the Middle East, spearheaded by Elia Zureik, Talal Asad, Huri Islamoglu-Inan, and Khaled Fahmy. Another concerns civil society which, in the context of Middle Eastern studies, is usually seen as both an antidote to the State and a factor in democratizing it. Major works in this direction are led by Saad Eddin Ibrahim's series of reports on civil society and democracy in various countries of the region, and similar collections of reports edited by Jillian Schwedler and Augustus R. (*c.*1995). A third direction of research focuses on state rituals and symbolism, a good example of which is Peter Chelkowski and Hamid Dabashi's study of the Iranian post-revolutionary State, *Staging a Revolution* (1999). Also significant in this genre is Lisa Wedeen's *The Ambiguities of Domination* (1999), which employs ethnographic methods to study the nuances of popular responses to state symbolism in Syria. Earlier important studies in this genre by Sami Zubaida (1989), Ernest Gellner (1981) and Clifford Geertz focus on the state appropriation of popular beliefs, and demonstrated how the State tends to cause religious ideology and symbols to become more rigid and orthodox when it adopts them for its own use.

These studies have helped move the center of gravity in the sociological study of the Middle East away from a focus on formal institutions and historical continuities, to a focus on the determining relations between social structures and social movements. Hanna Batatu's classic *The Old Social Classes and the Revolutionary Movements of Iraq* (1978), as well his more recent work on Syria, combines Marxist and Weberian perspectives to show how modern social movements could be understood in terms of the transformation in the basis of status groups from tribal, religious, and official dignitaries to landed aristocratic and merchant capitalist classes.

Batatu's landmark study hails from a new trend which rejects a well-established view of religion as pre-constitutive and internal to the culture. That view is not only common in orientalist tracts, but also in a tradition of sociological commentary ranging from Reuben Levy to S.N. Eisenstadt,

and is well represented in the contemporary *Fundamentalisms Project*, edited by Martin Marty and Scott Appleby. More recent trends by such anthropologists as Talal Asad (1993) and Ralph Coury treat both Islam and culture as dependent variables, and stress the historical dynamism and multiplicity of both. With respect to modernity, Talal Asad shows how religion itself can foster modernizing tendencies, and Ernest Gellner, who had otherwise stressed the similarities across Muslim societies and the pre-constitutive role of religion, also comes to argue the special closeness of Islam to the spirit of modernity, and its ability to encompass various types of social structures.

Many observers, however, continue to be deeply interested in the dynamics operating between more permanent historical social structures and contemporary ideologies and social movements. Sami Zubaida's work stands out in this regard as an exposition of the complexity of determining forces, and for demonstrating the need for an integrated analytical grid of cultural, sociological, comparative, and historical knowledge to apprehend the nuances of modern movements. Other scholars emphasize the determining role of specific sub-State social formations, such as the Ottoman *Millet* system, whereby various religious communities related to the State as recognized and legally autonomous corporate bodies. Main research questions in this regard concern the extent to which such a system gave rise to or inhibited the full expression of modern movements, such as nationalism, sectarianism, or secularism.

Scholars of the region are increasingly inclined to regard seemingly 'premodern' identities expressed in the political culture of the region as actually *modern* inventions. They also tend to stress the rootedness of modern social movements in external stimuli, such as colonialism and foreign influence. An important recent example of this scholarly trend is Ussama Makdisi's *The Culture of Sectarianism* (2000). Focusing on nineteenth-century Lebanon, Makdisi shows how confessional identities along which the modern Lebanese system was built were manifestations of various processes of modernity rather than expressions of reaction to it, and how they were fostered by Western intervention rather than emerging on their own. Elizabeth Thompson's *Colonial Citizens* (2000) shows how it was the intrusion of colonial powers, rather than indigenous traditionalism, that had been detrimental to both women and liberal thought, generally in Syria and Lebanon. Lacking roots in the colonies and conceiving of them as largely tradition-bound territories, colonial powers weakened indigenous liberalism, because the latter adhered to anticolonial nationalism, and strengthened, through its compensatory alliance with them, the more conservative forces, whose influence had been declining before the advent of colonialism.

Many commentators also view the emergence of modern nationalism, in particular, in the context of colonialism rather than that of indigenous developments. Because of its extremity, the case of the Palestinians is usually cited as the most evident, but by no means the only, illustration of this centrality of external intervening factors to the framing of modern identities. An important study in this regard is Rosemary Sayigh's *Palestinians: From Peasants to Revolutionaries* (1979), which uses oral history to show the growth of nationalism due to external colonizing pressure. A more recent work along these lines is Rashid Khalidi's *Palestinian Identity* (1997), which shows the gradual emergence of that identity in reaction to Jewish nationalism in Palestine. Similarly, in examining the Palestinian *Intifida*, Samih Farsoun and Jean Landis reject the relevance of most trends in social movement theory, emphasizing instead on the global context of the Palestinian struggle.

The pivotal geopolitical status of the modern Middle East, which entailed massive foreign intervention and a plethora of movements of resistance as well as political fragmentation, gave rise to a rich tradition of engaged scholarship on social movements. Khalil Nakhleh (1977) a Palestinian sociologist, has rejected outright any possibility of nonreflexive, detached, 'normal,' or 'nonnative' sociology under current circumstances in the region. Other scholars have sought to outline oppositional social movements in terms which endow them with an under-explored sense of agency. Examples of this approach include Joel Beinin and Zachary Lockman's *Workers on the Nile* (1987), and Anouar Abdel-Malek's *Contemporary Arab Political Thought* (1983), which moves away from cultural and structural determinism altogether and stresses the priority of agency under modern circumstances.

Social Movements and Social Change

Apart from questions of colonial encounter and political economy, an important line of emphasis in studying social movements in the Middle East concerns how they make use of cultural symbols. Julia Clancy-Smith's *Rebel and Saint* (1994) shows how resistance to colonialism in North Africa used icons and authorities from traditional settings whose function in society had until then been quite apolitical. In a nuanced analysis of the new veil and work environments in Cairo, Arlene Elowe Macleod (1991) shows how the veil today, far from being simply a patriarchal imposition, is actually used proactively by women to express various messages combining both accommodation and protest.

These studies stem from a very weighty orientation in Middle East studies, particularly in Middle Eastern countries, toward questions of heritage and its connection to modernity. Many important contemporary commentators, such as Fazlur Rahman, Seyyed Hossein Nasr, Syed M.N. al-Attas, and Ismail al-Faruqi have revisited classical Islamic philosophy and science in a quest to reveal a specifically Islamic philosophy of knowledge and science in tune with modernity. More politically inclined contemporary philosopher-activists (frequently Shi'ites), such as Ali Shariati, Mohammed Baqr al-Sadr, and Morteza Motahhari, have also revisited classical sources extensively in order to show the compatibility of Islam with modern ideologies, notably socialism and anticolonial nationalism. The same is true of Tayyib Tazzini's and Hussein Muruwwah's secular reading of the heritage. The voluminous contributions of the latter who was killed by Amal fighters in Beirut in 1985 were geared toward showing how classical Islamic philosophy and thought had always housed 'materialist' perspectives and methods in tune with Marxist dialectics.

Many other commentators are equally interested in voluminous, encyclopedic surveys of classical thought, but emphasize organizing principles as discursive, semiological, and hermeneutic rather than being socio-historical approaches. These include Muhammad Abid al-Jabiri's analysis over many volumes of the structures of knowledge in Arab culture and

poet Adonis's (Ahmad Ali Sa'id) equally critical study of imitation and originality in Arab culture, *The Permanent and the Changeable* (1974). While many of these studies seek to discover through historical investigation a root cause of contemporary 'stagnation' or 'backwardness,' many more seek to reveal through the same method the dynamism and adaptability of the heritage to various social structures and ideological claims. This latter approach to the heritage had required an abandonment of the philological and preconstitutive approach of orientalism. Among the most important founders of this critical approach is Muhammad Arkoun, whose pioneering studies of the Qur'an have emphasized the value of other than purely philological approaches to the holy text, such as anthropological, sociological, and semiological approaches. Mohammed Bamyeh's *The Social Origins of Islam* (1999) builds on that tradition of combined methods of reading, arguing that the growth of Islam was precisely due to an ability exhibited at its founding phase to accommodate the worldviews of different and even discordant social classes and types of social structure. Abdul-Kabir al-Khatibi echoes a similar theme when he argues that Islam must be seen as a sort of 'compromise' religion, and that its historical vitality stems from that attitude rather than from an alleged orthodox base and orientation.

In light of these new perspectives, the question arises again as to why this demonstrated dynamism of the heritage has not lent itself to a more vocal communion with liberal European modernity. Many responses to this question tend to dismiss it outright, citing as its faulty premise a Eurocentric tendency to outline various historical trajectories as more sharply differentiated than they actually were. In his critique of Eurocentrism, Samir Amin builds on and extends Martin Bernal's thesis in *Black Athena* (1987). Amin contests European fabrication of a monopolistic claim on Greek heritage, as well as the construction of European history through a direct line that flows from Greece to Rome. This perspective, according to him, ignores the larger Mediterranean contexts of classic civilization and the continuity and further development of Greek political and philosophical thought, as well as mathematics, medicine, and science in the Islamic world during Europe's Middle Ages.

Criticism of the tendency to view Middle Eastern or Islamic history in terms too distinct from other world histories has also been levied by the urban historian and sociologist Janet Abu-Lughod (1989) who, after her initial study of Cairo, came to repudiate the notion that there was anything specifically Islamic about the 'Islamic city.' For others, such as Jabiri and Hichem Djait (1974) the point became less relevant, as they identify the important lines of demarcation with respect to modernity not along large East/West types of categories. Rather, they prefer subregional categories, such as Arab Mashreq (Western Asia and Egypt), versus Arab Maghreb (rest of North Africa). Djait argues that the relatively more intense and enduring colonialism experienced by the Maghreb caused a more cultural proximity to modernity, since all illusions about self and society were destroyed through a colonial uprooting that had not been as severe in the Mashreq. The latter, being politically more advanced, had obtained its independence earlier than the Maghreb had and proceeded to be governed by dictatorial regimes. That condition, according to Djait, favored the construction of more illusions about self and society in the Mashreq, and thus more relative distance from the spirit of modernity.

Within discussion of the proper attitude to modernity, the question of gender has had a particular resonance. The feminist sociologist Fatima Mernissi attained fame by blaming Islam itself for perpetuating a retrograde attitude toward women. An alternative trajectory within feminist writings on Islam, represented in the works of Leila Ahmed, Nawal Sa'dawi, and Denise Spellberg, offers more complex readings of the role of women in Islamic history and places more emphasis on the agency of women. More recent trends have de-emphasized the alleged role of traditional religion even further as an explanatory factor. Deniz Kandiyoti's (1991) work has contributed to shifting attention away from religion as such and into patriarchal structures as sources of the oppression of women. Hisham Sharabi's pioneering study *Neopatriarchy: A Theory of Distorted Change in Arab Society* (1988) singles out structural changes within the Arab World as well as elsewhere within the past century that had led to 'neopatriarchy' instead of modernity. Neopatriarchy is explained by Sharabi as a form of patriarchy produced by dependent capitalism and social change lacking in a sense of authenticity. Thus neopatriarchy tends to distort modernization and nervously presents itself as the only valid option.

Given the magnitude of social, political, economic, and cultural transformations in the Middle East over the twentieth century, many social scientists will find some literary works very useful in apprehending change in certain areas. Three particular novelists stand out for their ability to reconstruct history and society in more overarching and encyclopedic ways than has so far been possible in the social sciences, and thus are worthy of greater attention. Adbelrahman Munif's (1989) multivolume epic *Cities of Salt* reconstructs in elaborate and patient detail the coming into being of Saudi Arabia in the 1930s, following the discovery of oil in the country by Western companies. The novel documents transformations in social relations and customs, the introduction of wage labor on top of an austere, seminomadic economy, the emergence of a dynasty and a State, the resulting tensions between authenticity and inauthenticity in public imagination, and other fascinating details which are usually glossed over in more dispassionate sociological and historical writings.

Gamal Ghitani's historical novel *Zayni Barakat* (1990), set at the time of Ottoman's takeover of Egypt from the Mamluks early in the sixteenth century, reconstructs elements of continuity and change in political structure as well as in the relationship between spiritual and political authority over the time-span of the two systems. Finally Nobel laureate Naguib Mahfuz's prolific career is dedicated to an elaborate and highly nuanced reconstruction of social psychology and its connection to mores and traditions. Characters in Mahfuz's works, who frequently mimic middle- and lower-middle class inhabitants of Cairo's neighborhoods, are usually shown as agents of their own destinies rather than as victims of established structures, and are capable of using a wide reservoir of proverbs and customary allowances of deviance to justify their actions. This holds true even in their attitude toward fate. In analyzing one famous story by Mahfuz, Halim Barakat shows that when characters claim what they are doing to be ordained by some fate, they are usually using the language of fatalism as a tool of

self-assertion, rather than as an explanation of their powerlessness with respect to established patterns of relations and social expectations. At both the macro and micro levels, these works combine research orientations central to understanding Middle Eastern society and history. These orientations involve political economy, social and institutional structures and mentalities, and the flexible morality governing everyday street-level interactions.

Conclusion

The study of society and history of the Middle East has gradually moved from focus on homogeneity and continuity to more elaborate discussions of the impact of many determining factors. It is now commonly accepted that due to its historical centrality to historical world systems and its contemporary geopolitical significance, Middle Eastern society and history cannot be understood apart from global trends which influence the region and are influenced by it as well. The studies are most revealing when they go above or below contemporary state jurisdictions and emphasize instead on the historically autonomous mode of self-organization of civil society, cultural communities, travel, and trade. Middle Eastern society has historically been defined more so by the hybridity and diversity resulting from the above factors, than by the social engineering of States.

Near-Infrared Spectroscopy

Judit Gervain, Centre National de la Recherche Scientifique (CNRS), Université Paris Descartes, Paris, France

Abstract

Near-infrared spectroscopy (NIRS) is a relatively new and increasingly widespread brain imaging technique, particularly suitable for use with young infants. The technique employs near-infrared light to assess the concentration changes of oxygenated and deoxygenated hemoglobin, accompanying local brain activity. The basic physical, physiological, and neural principles underlying the use of NIRS and some of the existing developmental studies are reviewed. Issues concerning technological improvements, parameter optimization, possible experimental designs, and data analysis techniques are also discussed and illustrated.

Introduction

One of the greatest advances in the recent history of the social and cognitive sciences has been the refinement and increasingly more versatile application of brain imaging techniques. Different methods measuring the electrophysiological (e.g., electroencephalography (EEG), magnetic encephalography (MEG)) or metabolic (e.g., magnetic resonance imaging (MRI), positron emission tomography (PET), near-infrared spectroscopy (NIRS)) aspects of neural activity have been used with a wide range of healthy and clinical populations to explore brain organization and function noninvasively in behaving participants.

NIRS is one of the most recently developed such technique. It consists of using near-infrared light to assess the concentration changes of oxygenated and deoxygenated hemoglobin (oxyHb and deoxyHb, respectively), accompanying local brain activity. Although the principles of using light to image the brain had been first laid down almost 40 years ago (Jobsis, 1977), the technique has only been used in cognitive neuroscience research for the last 15–20 years. While it can be applied to participants of any age, NIRS is most commonly used for brain imaging in the youngest developmental populations, including preterm and full-term newborns and young infants. Several of its features make it an ideal method for these age groups. Infants' tissues, e.g., skin, skull, etc., are thinner than those of older children and adults, allowing NIRS to probe deeper into the brain in these young participants. NIRS is also highly noninvasive and safe: it does not require the use of any isotope, carrier substance, gel, or other contact agent. It is noiseless and involves no strong magnetic field. It is easy to use and apply: the headgear containing the optical sensors is usually a comfortable, soft cap which can be placed on participants' heads in a matter of a few seconds. It is also highly tolerant to movement and motion artifacts, a constant problem for imaging participants who cannot easily follow verbal instructions. Most NIRS systems are small and often portable (some even have stand-alone headgear that wirelessly transmits information to the data acquisition system), allowing bedside or in-the-home testing. Mainly relying on the high motion tolerance and portability of NIRS, additional applications include clinical monitoring and bedside testing of brain function in patients who cannot be transferred to other imaging facilities, like a PET or an MRI scanner, as well as probing brain function in participants practicing sports or performing other physical action.

While a relatively recent imaging technique, NIRS has already provided significant empirical contributions to our understanding of cognitive and neural development from birth through infancy and early childhood. These, reviewed in detail below, include the origins of the brain specialization for speech and language processing (e.g., Gervain et al., 2008; Minagawa-Kawai et al., 2011a; Peña et al., 2003; Telkemeyer et al., 2009), the neural correlates of the development of face perception and social cognition (e.g., Blasi et al., 2007; Csibra et al., 2004; Lloyd-Fox et al., 2009b; Otsuka et al., 2007), multisensory processing (e.g., Bortfeld et al., 2007; Taga and Asakawa, 2007), and the assessment of brain function and oxygenation in preterm infants and infants having suffered perinatal trauma (e.g., Chen et al., 2002; Mahmoudzadeh et al., 2013).

Below, the basic principles and different technological implementations of near-infrared optical imaging will be discussed first. NIRS will then be compared to other brain imaging modalities. This will be followed by an overview of the existing NIRS literature, focusing mostly on developmental work. Next, technical issues relating to the practical application of NIRS will be discussed. This will be followed by a discussion of experimental designs and data analysis techniques suitable for NIRS. Finally, future directions will be outlined.

The Basic Principles of NIRS

Neural activity is accompanied by changes in blood oxygenation, which can be detected by near-infrared light. Optical imaging is thus an indirect measure of neural activity (with the exception of fast NIRS, see below), like fMRI, but unlike more direct electrophysiological measures such as EEG and MEG. The following review articles provide more detailed discussions about the physical and physiological principles underlying optical imaging (Aslin and Mehler, 2005; Chance et al., 1992; Ferrari et al., 2004; Gervain et al., 2011; Hiraoka et al., 1993; Lloyd-Fox et al., 2010; Minagawa-Kawai et al., 2008; Villringer and Chance, 1997). Below, we provide a brief overview of the most basic principles.

Continuous Light Optical Imaging

The most commonly used NIRS technique relies on continuous wave (CW), monochromatic near-infrared light to monitor the changes in the concentration of oxyHb, deoxyHb, or cytochrome *c* oxidase in brain tissue, related to neural activity.

When monochromatic light travels through a medium, some of it is absorbed, some of it is scattered, and some of it is transmitted, i.e., continues its trajectory unaffected by the medium. Exactly what proportions of the light are absorbed, scattered, and transmitted depend on the properties of the medium (e.g., absorption coefficient, concentration, etc.) and the light (e.g., wavelength, etc.). Biological tissues like the skin, the skull, and the brain are highly scattering media, causing light to travel in a nonstraight line. A physical law, known as the modified Beer–Lambert law, describes the relation between the relevant factors:

$$A = -log(I/I_0) = (c \times \varepsilon_\lambda \times l \times DPF) + G \qquad [1]$$

where A is absorbance, I is the intensity of the transmitted light, i.e., the light after the medium, I_0 is the intensity of the incident light, i.e., the light before the medium, c is the concentration or density of the medium, ε_λ is the molar extinction coefficient characteristic of the medium for a light of wavelength λ, l is the length of the medium in the dimension along which light travels, DPF is the differential path length factor that accounts for the nonlinear trajectory of light in biological media, and G is the scatter. Given this equation, the concentration of the medium can be obtained by measuring the intensity of the light that leaves the medium, assuming that the original light intensity, the length of the medium, and the molar extinction coefficient are known. Since the concentrations of oxyHb and deoxyHb in brain tissue are indicators of neural activity, we can use the above equation to calculate their concentrations by shining light of an appropriate wavelength and a known intensity on the head and measuring the intensity of the exiting light.

Using CW techniques, the actual scatter and the DPF cannot be measured directly. As a consequence, absolute values for the concentrations of oxyHb and deoxyHb cannot be obtained. However, the scatter is constant and can thus be mathematically eliminated when changes in the concentration of oxyHb and deoxyHb are calculated.

$$\Delta A = \left(\left(\Delta c_{oxy} \times \varepsilon_{\lambda_{oxy}}\right) + \left(\Delta c_{deoxy} \times \varepsilon_{\lambda_{deoxy}}\right)\right) \times l \times DPF \qquad [2]$$

The molar extinction coefficients of oxyHb and deoxyHb are shown in Figure 1.

The red and near-infrared range of the spectrum, encircled in Figure 1, contains the most adequate wavelengths for the optical imaging of biological media, because intervening tissues (e.g., skin, bone) are relatively transparent to light at these wavelengths. As mentioned before, the CW technique cannot directly measure the DPF, although estimates exist for the newborn and infant brain (Duncan et al., 1996; Wyatt et al., 1990). In addition, the distance that the light travels in the brain depends on l, which, in the case of NIRS applied to the human head, corresponds to the separation between the light source and the light detector locations on the surface of the scalp. Earlier NIRS systems usually applied one source and one detector, or optode, pair, constituting one measurement channel. Since then, multichannel systems have appeared using several sources and detectors.

Figure 1 The molar extinction coefficients of oxyHb and deoxyHb for different wavelengths of light. Encircled in black is the region of the spectrum that is most relevant for NIRS, with the isosbestic point of oxyHb and deoxyHb.

The availability of multiple channels has given rise to two distinct types of techniques: optical topography and optical tomography. The former provides a two-dimensional sampling from the surface of the cortex, whereas the latter, rarely used in experimental research due to technical limitations, allows a three-dimensional reconstruction of the hemodynamic signals from the brain. In topography systems, the coupled sources and detectors forming channels are located at a distance of a few centimeters from one another and the light travels through a banana-shaped trajectory (Figure 2), penetrating the surface of the cortex at a depth of a few millimeters. In young infants, whose surface tissues are thin, NIR light can penetrate as deep as 30 mm into the head (measured from the scalp surface), thus 10–15 mm into the cortex at a source–detector separation of 3 cm, whereas in adults, the penetration into the cortex is only about 3–5 mm deep with the same separation.

Figure 2 A schematic illustration of the trajectory of near-infrared light in the human head at different source–detector separations.

CW systems thus use changes in oxyHb, deoxyHb, and totalHb (the sum of oxyHb and deoxyHb) concentrations as an indirect measure of brain activity. This is possible because there is a relationship between focal brain activity and regional cerebral blood volume and flow. This neurovascular coupling means that increased activity, requiring additional metabolic supplies, e.g., oxygen and glucose, is accompanied by local vasodilation, increased blood flow, and oxygenation. Crucially, the increase in blood flow and oxygen exceeds the demands, resulting in a local and transient excess of oxygen. This metabolic response, known as the hemodynamic response function (HRF), follows local neural activity by several seconds and the exact physiological mechanisms relating the HRF to neural firing are not fully understood (Logothetis et al., 2001; Magistretti, 2006). While the shape of the HRF for adults is well described (an increase in oxyHb concentration several seconds after stimulation, a somewhat later-peaking decrease in deoxyHb concentration, and a slow return to baseline, with possible over- and undershoots, for both Hb species; Boden et al., 2007; Obrig et al., 2000), less is known about its shape in developmental populations. The HRF might be delayed, slower to peak, and/or slower to return to baseline in infants than in adults (Meek, 2002). The slowness of the HRF needs to be taken into account when designing NIRS experiments (see below).

Measuring relative oxyHb and deoxyHb concentrations is usually sufficient for research-related applications of NIRS. However, whenever absolute concentration values are relevant, e.g., in clinical settings, non-CW techniques, developed to estimate the path length and/or the scatter, need to be used. Two such methods include the intensity-modulated or frequency-resolved technique and the time-of-flight or time-resolved technique.

Frequency-Resolved Optical Imaging

In frequency-resolved NIRS, the intensity of the light is modulated at a certain frequency. While traveling through tissues, the intensity is attenuated and the phase of the modulation is shifted due to scattering. By measuring the attenuation and the phase-shift, the path length and the scatter can be determined, allowing the calculation of absolute oxyHb and deoxyHb concentration values (Chance et al., 1990). There are commercially available systems based on this approach (for an overview of commercially available systems, see Lloyd-Fox et al., 2010; Wolf et al., 2007). However, they typically have lower sampling rates and higher costs than the CW systems.

Time-Resolved Optical Imaging

Another approach for determining the path length of light in biological tissue is to use single light pulses instead of continuous light. When a very short pulse of light is sent through tissues, the time distribution of individual photons that leave the head can be registered by a detector or photon-camera. The average time-of-flight of the photons is then multiplied by the speed of light to determine the mean path length (Delpy et al., 1988; Lloyd-Fox et al., 2010; Wolf et al., 2007). This technique offers slower data acquisition than most CW systems.

Fast Optical Imaging

Unlike the previous three techniques, which measure the metabolic correlates of brain activity, fast optical imaging (also known as event-related optical signal, EROS) detects the changes in the optical properties of neurons and surrounding tissue during firing (Gratton and Fabiani, 2003, 1998; Tse et al., 2007). As this measure is a correlate of the electrophysiological activity of neurons and not of metabolism, it is a much faster signal, with a latency in the millisecond range, comparable to that of electrophysiological techniques. This fast signal and the slow metabolic response can be detected using the same equipment, which could provide an ideal method to characterize neural activity with high temporal and spatial resolution at the same time. However, the reliability and strength of this fast optical signal as measured noninvasively in behaving adult subjects may be limited, at least with the currently available technologies (Steinbrink et al., 2005). The remainder of this article will concentrate on the three metabolic NIRS techniques and will mostly ignore fast NIRS.

NIRS as Compared to Other Imaging Techniques

When compared to other brain imaging and electrophysiological techniques, NIRS has several clear advantages, in particular when used with infants. Unlike the magnetic gradients used in MRI, NIRS is completely silent, providing a nonintrusive environment and allowing for an easy presentation of auditory stimuli. No strong magnetic field or radio frequency pulses are involved, alleviating safety concerns. In terms of the obtained signal, NIRS has the advantage of measuring both oxyHb and deoxyHb changes, providing a physiologically plausible measure of blood flow and volume, while the blood oxygen level dependent (BOLD) response in fMRI is related to deoxyHb only. The costs of NIRS are also considerably lower than those of MRI.

As compared to EEG, NIRS provides better spatial localization, as most topographic implementations of NIRS are not subject to the inverse problem associated with source localization of electrical potentials from the scalp. NIRS is also less sensitive to motion artifacts than both MRI and EEG. While the time resolution of NIRS is lower than that of EEG, the sampling rate of most CW machines is around 10 Hz compared to 0.5 Hz in fMRI, allowing for an improvement in temporal resolution, once mathematical algorithms are in place to adequately analyze event-related data. PET, single-photon emission computed tomography (SPECT), and other nuclear imaging techniques require the use of isotopes and carrier substances, raising safety concerns for vulnerable populations.

The key limitation of NIRS is that it only probes the surface layers of the cortex. Consequently, brain structures that lie deeper in the cortex or below it are not visible in NIRS topography techniques. In addition, the temporal resolution of NIRS is lower than that of EEG, rendering the detection of fast responses to single events more challenging. Similarly, the spatial resolution of NIRS is inferior to that of MRI.

An exciting new avenue to overcome some of the shortcomings of NIRS, e.g., its low temporal resolution, while taking full advantage of its strengths, is to combine it with other measures, such as EEG. Indeed, several recent NIRS–EEG

studies (Mahmoudzadeh et al., 2013; Telkemeyer et al., 2011, 2009), mainly investigating speech perception in newborns and infants, have proven the feasibility of such corecording approaches.

What NIRS Has Taught Us: A Brief Summary of the Existing NIRS Literature

As discussed above, the advantages of NIRS make it an ideal tool for brain imaging in young infants, whereas adults can be safely and successfully imaged using techniques that are more constraining, but offer better spatial or temporal resolution. Consequently, NIRS has mainly been used in developmental neuroscience research in the last 15 years. A brief and non-exhaustive summary of this body of literature is provided below.

The Origins of the Functional Specialization of the Brain: Localization of Perceptual Abilities

The first studies used NIRS to establish the developmental origins of the brain specialization for different perceptual modalities. In one of the earliest studies with newborns, Sakatani et al. (1999) registered increased activation in the bilateral frontal lobes while infant participants listened to music. NIRS has also proven useful to register orbitofrontal brain activation in newborns during olfactory stimulation (Bartocci et al., 2000). Newborns between 6 h and 8 days old showed increased response to a vanilla scent as well as to the odor of their mother's colostrum as compared to water. The intensity of the response to colostrum attenuated with post-natal age, demonstrating the sensitivity of NIRS to detect a graded response. Probing visual perception, Taga et al. (2003) found an increased response in the occipital areas of 2–4-month-old infants while the infants were watching checkerboard pattern reversals. When measuring infants' responses to multiple sensory stimulation, studies (Bortfeld et al., 2007; Taga and Asakawa, 2007) found that NIRS was sensitive enough to detect brain responses specific to auditory stimulation while a simultaneous visual stimulus was also present, suggesting that NIRS has sufficient selectivity to localize neural activity triggered by different perceptual modalities. Similar results were later obtained by Bortfeld et al. (2009), who showed that the response to speech, even when presented together with visual stimulation, was left-lateralized in 6–9-month-old infants.

Early Lateralization and Functional Specialization for Language

The origin and developmental trajectory of the left lateralization of language, found in most right-handed adults (Kimura, 1967), is another functional, localizational question that has been addressed using NIRS. In a pioneering study, Peña et al. (2003) compared newborns' responses to three blocks of stimuli: forward-going infant-directed speech in the native language, the same stimuli played backwards, and silence. Newborns showed increased activation in the left temporal area in response to forward speech, but not to backward speech or silence. Similar results were obtained in an fMRI study with 3-month-old infants (Dehaene-Lambertz et al., 2002). Whether this lateralization is the reflection of familiarity with the native language due to exposure *in utero* or whether the left hemisphere is prepared to process language stimuli in general, including unfamiliar, nonnative languages, is currently heatedly debated. One line of research addressing this issue tested the processing of native and nonnative languages in newborns using NIRS. Some of these studies replicated the left lateralization for the native language, but found bilateral activation to a nonnative language (Sato et al., 2012), whereas other studies obtained bilateral activation for both the native and a nonnative language, with a difference only in response intensity in favor of the native language (May et al., 2011). A second line of research has focused on the physical/acoustic properties of the speech signal that might drive specialization. Different theoretical accounts (Hickok and Poeppel, 2007; Poeppel, 2003; Zatorre and Gandour, 2008; Zatorre et al., 1992) suggest that the temporal and spectral properties of speech might play an important role: the right hemisphere is believed to integrate over long time windows and/or spectral information, whereas the left hemisphere or both hemispheres might be responsible for precise temporal processing. Recent NIRS studies in young infants have provided mixed support for these hypotheses. Newborns, 3- and 6-month-old infants showed bilateral activation for fast-modulated stimuli and a right hemisphere advantage for slowly modulated sounds in an NIRS–EEG corecording study (Telkemeyer et al., 2011, 2009). However, no significant response was obtained for spectrally modulated stimuli (Minagawa-Kawai et al., 2011b). Thus the developmental origins of the brain specialization for speech processing remain an open question.

A different set of studies has addressed the lateralization of individual linguistic properties and language-specific phonological contrasts. These have been found to take several months of experience with the native language to lateralize, mirroring the behavioral transition in language perception during the first year of life from general, broad-based abilities toward enhanced sensitivity to the specifics of the native language (known as perceptual attunement). A study by Minagawa-Kawai et al. (2007) illustrates this attunement using the short–long vowel contrast in Japanese. Infants show a U-shaped discrimination curve, distinguishing the two categories at around 6–7 months and after 13–14 months, but not at around 10–11 months. Importantly, left lateralization in response to these stimuli, which is the typical adult pattern, appears only at around 13–14 months and approximates the exact adult spatial distribution after 25–28 months. These results suggest that left lateralization for the short–long vowel contrast emerges as the perception of the contrast is fine-tuned, shifting from a simple acoustic difference to a language-relevant phonological property. Another example comes from work by Sato et al. (2010), who investigated the development of the behavioral and neural response to Japanese pitch-accent patterns and their pure tone equivalents, which served as a nonlinguistic control. Behaviorally, both 4- and 10-month-old infants could discriminate the different pitch-accent patterns (high-low vs low-high). However, at 4 months, infants did not

show different NIRS responses to real Japanese words and their pure tone equivalents, suggesting that processing is acoustic/nonlinguistic at this age. At 10 months, by contrast, infants showed greater activation to a change in word pitch-accent patterns than to a change in the corresponding pure tone patterns, and this differential response was localized in the left hemisphere, indicating that processing was linguistic in nature.

A similar trend was found for the perception of prosody (the melodic property of speech that includes variations in pitch, intensity, and duration). Results with newborns (Saito et al., 2007a) indicate that they show increased frontal response to infant-directed speech as compared to adult-directed speech, allowing infants to tune into speech addressed to them early on. A key difference between the two speech registers is the highly variable, exaggerated prosody in infant-directed speech, which might explain the more prominent activation found for this stimulus. Indeed, in another study, the same authors (Saito et al., 2007b) showed that newborns can discriminate between normally intonated prosody and monotone speech with flat prosody, as they show increased activation in the bilateral frontal areas to the former, but not to the latter. While the frontal areas do not show lateralization at this early stage, Homae et al. (2007, 2006) found that at 3 months, infants show greater activation in the right temporoparietal areas to normally intonated speech as compared to speech with flattened prosody. Wartenburger et al. (2007) provided converging evidence for a hemispheric specialization to different aspects of speech processing. Testing 4-year-old children, they found that when prosody is presented devoid of linguistic content, triggering nonlinguistic processing, the right frontotemporal areas are involved, whereas presenting the same prosody together with the corresponding linguistic content engages the left hemisphere.

Investigating when the ability to process the structural properties of language begin, Gervain et al. (2008) found increased neural activity in the bilateral temporal and left frontal areas of newborns when they listened to speech that followed a structural rule (ABB: e.g., 'mubaba') as compared to unstructured speech (ABC: 'mubage'). The activation was more pronounced in the left than in the right temporal area, reproducing previous lateralization results. These results have been expanded by Gervain et al. (2012), who investigated the perception of sequence-initial versus sequence-final immediate repetitions (AAB vs ABB) and found that they were discriminated by the newborn brain.

Recent studies on language processing have also used NIRS systems with a large number of channels to establish functional connectivity and to identify the language network within the brain. In two studies, Homae et al. (2011, 2010) have tracked the development of global cortical networks at rest, as well as during and after speech stimulation at birth, 3 and 6 months. They have found that resting state connectivity increases within and between hemispheres in the occipital, parietal, and temporal lobes, but reduces in the frontal lobe over development. During speech stimulation, 3-month-olds showed increased connectivity between the channels in the temporal and temporoparietal, in particular within the same hemisphere. Interestingly, higher connectivity was maintained between the frontal and temporal areas during rest following speech stimulation as compared to the resting period before stimulation, indicating the existence of a memory/storage network.

Cognitive Development

Nonlinguistic cognitive functions have also been explored using NIRS. One of the first studies (Baird et al., 2002) investigated the neural correlates of object permanence in a longitudinal study with 5–12-month-old infants. Infants were tested behaviorally for the presence of object permanence while neural activity in their frontal cortex was recorded using NIRS. NIRS data from the session where the infant first showed object permanence behaviorally were compared to NIRS data from the preceding session. Increased activation was observed in the object permanence sessions as compared to the prepermanence ones. Object processing was also assessed by NIRS (Wilcox et al., 2009, 2008). Infants were presented with physically possible and impossible events involving object movement and identity. The possible event involved two different objects emerging from either side of a wide occluder, whereas the impossible event involved the same two objects emerging from behind an occluder that was too narrow to hide two objects. The featural differences between the objects were systematically manipulated. The objects either differed in multiple features, or only shape or color, or they were identical. In the occipital areas, all four conditions gave rise to similar activations, while in the inferior temporal areas, only the multifeatural and shape change conditions evoked increased responses.

In the social domain, Csibra et al. (2004) found a difference between neural activation in the occipital cortex in response to faces versus visual noise stimuli in adults and 4-month-old infants. A second study (Blasi et al., 2007), which repeated this paradigm, but used a multiple channel array (rather than a dual channel array), allowed a wider cortical region to be investigated. This study replicated the results of the adult study, finding significant increases in oxyHb concentration to the face stimuli and not to visual noise. A later study by Otsuka et al. (2007) found a brain signature for the face inversion effect, i.e., the fact that while upright faces are special, preferred stimuli, processed by a dedicated brain area from a very young age, inverted faces are not privileged. The authors compared activation in the left and right temporal areas while 5–8-month-old infants were watching upright faces, inverted faces, or objects. They found increased activation in the right temporal areas in response to upright, but not to inverted faces. The same group of authors (Nakato et al., 2009) also explored the neural mechanisms underlying the development of view-invariance in face perception. Five-month-olds showed increased activation in the previously identified right temporal areas for front views of faces only, not for profile views, but by 8 months, increased activation emerges for the latter type of stimuli as well, indicating the emergence of view-invariance between these two ages.

Investigating the perception of dynamic visual social cues, Lloyd-Fox et al. (2009) found that 5-month-olds showed increased cortical activation in response to dynamic social stimuli (such as 'Peek-a-boo') in the bilateral superior

temporal and inferior frontal regions of the cortex. Importantly, this response was not found to dynamic nonsocial stimuli (such as mechanical toys), suggesting that the response was to the social component and not simply to movement. A study (Grossmann et al., 2008) investigating eye gaze perception with an accompanying smile cue in 4-month-olds found larger activation in infants' prefrontal cortex and right superior temporal region in response to a gaze shift toward, but not away from, the infant.

NIRS in Clinical Populations

NIRS is also increasingly used in clinical pediatric practice, providing a useful tool for the functional assessment of infants with different medical conditions or at risk for developmental disorders. An early example of such work comes from Chen et al.'s (2002) study, who compared healthy newborns' brain response to auditory stimulation with that of newborns suffering from hypoxic-ischemic encephalopathy. Normal newborns showed increased oxyHb and totalHb concentrations in the frontal areas during stimulation, whereas about two-thirds of the newborns with hypoxia/ischemia exhibited a decrease in oxyHb and totalHb concentrations, the extent of which negatively correlated with the severity of the pathology. More recently, NIRS has also been used to assess brain functions in preterm newborns. Mahmoudzadeh et al. (2013) have found that when exposed to speech, the brain of preterm infants born at 28–32 weeks gestational age already showed important similarities with the functional organization of the adult brain. This is all the more remarkable, as at this early stage of preterm development, not all cortical layers of the brain are yet formed. NIRS has also proven useful in assessing developmental disorders such as autism in young infants. As autism spectrum disorder has a strong genetic component, the younger siblings of children with autism are themselves at risk, but a stable diagnosis is not possible before 3 years of age. A recent NIRS study, however, has found that already during the first 6 months of life, infants at risk for autism show a reduced neural response to visual and auditory social stimuli as compared to typical controls (Lloyd-Fox et al., 2013), suggesting it might be possible in the future to identify brain signatures for certain developmental disorders even before overt behavioral markers become observable.

Technical and Methodological Considerations

As noted before, NIRS is an increasingly popular, but still relatively recent imaging technique. As a consequence, some technical, technological, and methodological issues are not fully standardized, and different practices coexist. Below, some of these points are discussed, with the aim of providing a useful starting point when planning or interpreting NIRS studies.

Probe Design and Source–Detector Separation

Unlike fMRI and PET, but like EEG, NIRS systems are equipped with a headgear that can be flexibly positioned on the participant's head, and in many systems, the headgear itself is also configurable, e.g., in terms of the number of optodes used or the relative distance between light sources and detectors. This flexibility allows experimenters to adapt to a large number of different research questions and populations. At the same time, finding the optimal design requires careful consideration of a number of factors.

One such factor is the distance between sources and detectors. In NIRS systems, a measurement point or channel is not an actual physical entity. Rather, it is the coupling of a light source and a detector, which sample from the biological tissues under the space between the two optodes. The source–detector separation is an important parameter of NIRS systems, as it determines the depth of penetration, as well as the spatial resolution. Larger separations sample from areas deeper in the cortex (the arc of the banana-shape sampled from is larger, see **Figure 2**), providing more information about neural activity. However, because the trajectory of the light is longer and it goes through more nonbrain tissues, the signal-to-noise ratio typically decreases with increasing separation. Further, larger separations decrease the spatial resolution of the measurements and allow for fewer channels to be placed on the participant's head (which is particularly relevant for young infants, whose head size is relatively small). The optimal source–detector separation is also influenced by technical parameters, such as the type of optical fibers used as well as by anatomical factors, such as the brain's distance from the scalp in a given head/brain region, the thickness of the skin and skull. Given all these factors, the optimal trade-off between penetration depth and spatial resolution in most systems is a source–detector separation between 2 and 5 cm. Most studies have used the same separation between all source–detector pairs, but a few studies have used several different separations (Blasi et al., 2007; Cristia et al., 2014; Gervain et al., 2011).

The regions of interest, where brain activity is expected to be obtained, is another relevant point to consider. Unlike EEG, NIRS is not subject to the inverse problem. In other words, the localization of brain activity as measured by NIRS is precise, even though spatial resolution is not particularly high (a few centimeters) and is mostly limited to the surface of the cortex. Existing fMRI studies can often be informative when determining the regions of interest to be targeted.

One final issue regarding the choice of headgear is the actual physical design. In young infants, who cannot follow instructions and cannot be expected to stay motionless for extended periods, the headgear plays a quintessential role in optimizing data quality. It needs to be easy to apply, light and comfortable to wear and, most importantly, it needs to ensure a stable attachment to the head such that the infant's movements should not displace the headgear with respect to the head. Additionally, it should allow the researcher to move hair out of the way, when necessary. Many NIRS systems use stretchy caps or soft, elastic straps to meet these criteria, but designing a good-fitting headgear remains one of the major challenges when working with young infants.

What Measure: OxyHb, DeoxyHb, and TotalHb

NIRS has the advantage of measuring both oxyHb and deoxyHb. The sum of the two, totalHb, is also often reported,

as it corresponds to the physiological measure of regional cerebral blood volume. Given the typical healthy adult HRF, oxyHb and deoxyHb should show concomitant changes in the opposite direction, reflecting the neurovascular coupling characteristic of brain activity.

However, in developmental studies, it is often the case that only one hemoglobin species is reported or shows significant changes as a function of stimulation. Some technical parameters, such as the material of the optical fibers used or the exact light wavelengths, certainly influence an NIRS system's differential sensitivity to the two hemoglobin species. Indeed, many infant studies, conducted with the currently available NIRS technologies, often report significant changes in the concentration of oxyHb only or report changes in the non-canonical direction for one or both hemoglobin species, i.e., an increase in deoxyHb or a decrease in oxyHb. Since the exact shape of the hemodynamic response in infants is not fully known, and to allow for better comparisons across studies, the best practice is to report both oxyHb and deoxyHb results, even when not significant.

A better understanding of the neurovascular coupling and the physiological basis of the hemodynamic response, as well as comparisons with the BOLD response measured by fMRI, originating from the paramagnetic properties of deoxyHb, will be necessary to fully clarify this question.

Brain Development

When working with infants and children, the populations most often tested with NIRS, brain development needs to be taken into account. Factors such as head size, synaptogenesis, and synaptic pruning as well as the myelination of the brain change over time. Vascularization and the relative position of the brain compared to the skull also change. As all these factors influence which brain structures are visible to NIRS at a given point in development, it is indispensable for researchers to formulate anatomically informed hypotheses. Further, comparisons across different age-groups require caution.

These problems are often exacerbated by the fact that NIRS probes are placed on the head using surface landmarks only, such as the ears or the vertex, since structural images of the participants' brains are typically not available.

One possible solution comes from the growing body of available MRI images of developmental brains. Several large-scale studies have recently been conducted resulting in searchable archives of MRI brain images from birth to adulthood (see list of relevant Web sites below). These allow developmental change along a relevant dimension to be measured and quantified, and can also serve as a basis for the assessment of individual variability within a developmental age. (Although, of course, the assessment of the actual variability among the participants of any specific study can only be precisely measured if brain scans are available for those individuals.)

Experimental Designs

The HRF is a slow, metabolic correlate of brain activity, peaking several seconds after the actual neural response. It is often assumed that in developmental populations, the response is even slower than in adults. This needs to be taken into account when designing NIRS experiments. The most straightforward and so far most popular way to circumvent this problem has been the use of block designs, also common in fMRI experiments. In a block design, a short stimulus is repeated or a longer stimulus is presented for a duration of up to several, often 10–20 s. To obtain a good signal-to-noise ratio, each experimental condition is presented in several blocks. Blocks are typically separated by extended baseline periods, e.g., 10–20 s, to allow the hemodynamic response to return to baseline. This design provides a robust signal, due to the additivity of the responses to the individual stimuli within a block, and it does not require mathematically sophisticated analyses. However, its temporal resolution is obviously quite low, and habituation/suppression or other task-related effects might occur due to the frequent repetition of the same or similar stimuli.

As NIRS machines typically have a relatively high sampling frequency (often around 10 Hz or above), it is also possible to conduct studies with event-related designs, allowing a much better temporal resolution than block designs. In event-related designs, single stimulus tokens are presented at random intervals. The interstimulus interval needs to be sufficient long to allow the response to return to baseline, but a few seconds are often enough, as the single-stimulus response itself is weaker and shorter than the block-response. This design is able to capture single-stimulus responses and fast events. At the same time, the obtained signal is relatively weak, which makes this paradigm somewhat less suited for infants, whose data are often noisy and heavily artifacted. In addition, data analysis with this design often requires complex mathematics, with assumptions about the shape of the hemodynamic response, which is not fully known in infants. Consequently, few developmental NIRS studies have used event-related designs.

Data Analysis and Interpretation

The analysis of imaging data typically consists of two steps: preprocessing, seeking to improve data quality, and statistical analysis, testing the experimental hypothesis. NIRS is no exception.

Although NIRS is more resistant to movement artifacts than other imaging methods, preprocessing is still an important step, especially when working with infants and children. NIRS data are most often band-pass filtered. The low-pass filter serves to exclude high-frequency physiological signals (around 1 Hz and above), such as the heartbeat, as well as high-frequency noise due to hair, etc., whereas the high-pass filter blocks slow baseline drifts and low-frequency oscillations due to systemic changes not related to experimental stimulation, such as changes in blood pressure, etc. Manual or automatic artifact rejection can also be necessary. It is facilitated by the fact that the hemodynamic response is relatively slow, while movement and other related artifacts are typically abrupt changes. Baseline correction is also a common procedure, whereby the mean signal intensity of a baseline period, recorded at the beginning of the entire time series or at the beginning of each individual trial, is subtracted from the data. This is another way to correct for overall shifts in systemic parameters influencing blood flow.

Two main methods have been used for the statistical analysis of experimental hypotheses. Mostly inspired by EEG, one option is time series averaging, whereby the responses to individual blocks/trials within one condition are averaged, and then the averages between conditions are statistically compared using t-tests or analyses of variance. Parameters most often compared are the amplitude, latency, or spatial localization of the responses, either to baseline or between the conditions. The other possibility, borrowed from fMRI research, is the use of a general linear model or statistical parametric mapping type of approach. The assumption behind these methods is that the NIRS data (Y) can be mathematically described as the sum of the weighed (β) contribution of different predictors (X) plus an error term (noise, ε), i.e., $Y = \beta_1 X + \beta_2 X + \ldots + \beta_n X + \varepsilon$. Predictors can be chosen as appropriate for the study design and research question, but minimally, they include a predictor for the response obtained as a boxcar function (sequences of 'on' and 'off' periods) representing the stimulation convolved with the HRF. One problem here is that the infant HRF is not well known, so studies often use the adult HRF instead, a less than ideal solution.

More recently, other statistical methods such as cross-correlations or phase information have also been used, e.g., to assess functional connectivity.

The canonical HRF, with an initial dip and a subsequent increase in oxyHb and a decrease in deoxyHb, results from a local and transient surplus of oxygen delivered by the vascular system to active brain tissue. For the correct interpretation of any NIRS data, it is thus important to realize that NIRS measures a metabolic and hence indirect correlate of neural activity. In other words, it is the metabolic 'cost' or effort that is assessed, not an actual neural response. Different NIRS signals, i.e., different metabolic costs, often imply different underlying neural mechanisms. The contrary is not necessarily true: similar HRFs do not necessarily indicate that the underlying neural mechanisms are the same. Relatedly, an activation seen in NIRS, i.e., an increase in oxyHb and a concomitant deoxyHb, might correspond to an excitatory or an inhibitory connection/relation at the neural level, as both excitation and inhibition have metabolic 'costs.' Thus, an activation pattern seen in NIRS cannot discriminate between the two.

A 'deactivation' pattern, i.e., a decrease in oxyHb and an increase in deoxyHb, is also sometimes observed. A noncanonical HRF should always be treated with caution. After all, a decrease in the oxygen supply of the brain is associated with traumatic events such as ischemia or a stroke. Therefore, we can only talk about genuine deactivation if there is reason to believe that a greater activation level was achieved prior to the measurement period, with respect to which a lower activation level, i.e., a relative decrease in oxyHb, is then observed during measurement. One situation in which this can occur is when the baseline period contains control stimuli that evoke a stronger response in a given brain region than the actual experimental stimuli. It is thus quite important to carefully consider the nature of the baseline or control stimuli. Other forms of noncanonical responses, e.g., when both hemoglobin species change in the same direction, are even harder to interpret from a physiological perspective, although such responses are sometimes observed in developmental populations. More research will be needed to fully understand nonadult HRF patterns.

Future Directions

NIRS is a relatively new, but increasingly popular brain imaging technique, which has found widespread use in developmental neuroscience. One important challenge that the NIRS community now faces is the need for more standardized procedures and methods, allowing for easier comparisons across different studies and populations. Coregistration with other imaging and experimental methods also offers an important new avenue for research. The investigation of the physiological basis of the NIRS signal, in particular in infants and children, will also be necessary for a better understanding of the complex relationships between neural, vascular, psychological, and behavioral processes.

Abstract

Joseph Needham (1900–95) was not only an excellent biochemist, but also an eminent historian. He became famous for his impressive achievement embodied in the massive series *Science and Civilisation in China*, published in many volumes since 1954. Although the exploration of the history of traditional Chinese science, technology, and medicine had begun already before him, he is certainly the scholar who contributed most to the academic institutionalization of these studies, both in East and West. One of his basic convictions was that modern science and technology, as they arose in the West, owed much to ideas and inventions originating in East Asia or China. He conceived of modern science as an outcome of a universalistic process, to which various cultures had made their contributions. In his opinion, the reason that modern science did not arise in China was because it was hindered by external factors, especially the structure of Chinese feudal-bureaucratic society. Needham's approaches provide important elements for a comparative historical and differential sociology of civilizational complexes and intercivilizational encounters. He not only ascribed social values to the notion of universality of modern science, but also perceived it as a sharp tool of critique directed against Eurocentric internalism.

Joseph Needham was not only an excellent scientist, but also an eminent historian. He became famous for his impressive achievement embodied in the massive series *Science and Civilisation in China* (SCC), published in many volumes since 1954. His work on this subject has deeply influenced not only research on the history of China, but also studies in the history of science, technology, and medicine in general. Although the exploration of the history of traditional Chinese science, technology, and medicine had begun already before him, he is certainly the scholar who contributed most to the institutionalization of these studies, resulting, both in East and West, in the foundation of specific academic research disciplines and institutes. One of his basic convictions was that *modern* science and technology, as they arose in the West, owed much to ideas and inventions originating in East Asia or China. He conceived of modern science as an outcome of an universalistic process, like a sea into which the rivers of various cultures had flowed, making their contributions. In his opinion, the reason that modern science did not arise in China was because it was hindered by external factors, that is, the structure of Chinese feudal-bureaucratic society.

Life

Needham was born in London on 9 December 1900, the only son of a physician and a musically talented mother. In 1918 he went to Gonville and Gaius College in Cambridge to study biochemistry, where he became a student and collaborator of Frederick Gowland Hopkins, a subsequent Nobel Prize winner in medicine. In 1924, he married the biochemist Dorothy Moyle. In 1931 Needham published *Chemical Embryology* in three volumes, a description, definition, and historical account of a new scientific discipline in which he had increasingly specialized. This was followed, in 1942, by *Biochemistry and Morphogenesis*. Already at an early stage in his career, Needham engaged in public debates about the relationships between science, religion, philosophy, history, and politics. In the period from 1925 to 1946, he wrote or edited such works as *Science, Religion, and Reality* (1925), *The Sceptical Biologist* (1926), *The Nazi Attack on International Science* (1941), *History is on Our Side* (1946), etc., the latter two attacking the Nazi abuse of science.

In 1937 a group of young Chinese scientists came to Cambridge, among them Lu Gwei-Djen, who later became one of his collaborators and, 2 years after the death of Dorothy Moyle in 1987, his second wife. These Chinese scientists aroused in him a deep interest in and fascination for Chinese culture and language. Needham started to learn Chinese privately with the help of a Cambridge professor of Sinology. In 1942, the British government commissioned him to go to China to establish the Sino-British Science Co-operation Office in Chongqing, the city to which the Chinese government had withdrawn in the face of the Japanese invasion. He spent more than 3 years in China, where, apart from his official duties, he started to collect information, literature, and source material on the history of science, technology, and medicine in China. From 1946 to 1948 Needham was appointed director of the department for science at UNESCO in Paris. In 1952 he was severely criticized for joining an international scientific committee, which on the invitation of the governments of North Korea, the People's Republic of China, and the communist-sponsored World Peace Council was commissioned to investigate charges of US biological warfare in the Korean War. The committee concluded that the US military had experimented with biological weapons, and Needham was subsequently reproached as having been deluded by communist propaganda and his love for China. As a consequence, he was shunned by many in the academic world, and was not permitted to visit the US in the coming years.

After his return to Cambridge in 1948 Needham all but gave up his scientific research, and turned instead to his great project SCC. The first volume was published in 1954. In the course of time, more than twenty collaborators from all parts of the world joined Needham to participate in this project. In 1968 Needham founded in Cambridge the East Asian History of Science Trust to preserve his library and continue his work. By 1987, funds had been raised to build a home for his library, the

Needham Research Institute, which was finally completed in 1991. Together with his first wife he was elected Fellow of the Royal Society (science) in 1941. Thirty years later, he also became Fellow of the British Academy (humanities). In 1968 the Society for History of Science and the Society for History of Technology honored him with the George Sarton Medal and the Leonardo da Vinci Medal, respectively. He was bearer of the Order of the Brilliant Star conferred on him by the People's Republic of China. Finally, in June 1992, his achievements were given official recognition when he was made Companion of Honour by Her Majesty the Queen. He died in Cambridge on 24 March 1995, at the age of 94.

Contribution to Knowledge and Intellectual Environment

Based on his ecumenical and universalistic view of the history of science and technology, in which the Old World must be taken as a whole, one of Needham's crucial and seemingly paradoxical problems was why modern science, the mathematization of hypotheses about Nature, with all its implications for advanced technology, made its meteoric rise only in the West at the time of Galileo. Of equal importance for him was the question of why it was that between the second century BC and the sixteenth century AD East Asian culture was much more efficient than the European West in applying human knowledge of Nature to useful purposes. How could it have been that the weakness of China in theory and geometrical systematization did not prevent the emergence of technological discoveries and inventions often far in advance of contemporary Europe? What were the inhibiting factors in the Chinese case that prevented a rise of modern science in Asia analogous to that which took place in Europe from the sixteenth century onward? And finally, how was it that Chinese backwardness in scientific theory coexisted with the growth of an organic philosophy of Nature, closely resembling that which modern science (in Whitehead's sense) had adopted after three centuries of mechanical materialism?

In order to find answers to these questions, Needham carried out enormous comparative research, not only dedicated to internalist interpretations of science and technology, but also taking into account influences from philosophy, language, religion, and ideology as well as social, economic, and geographical conditions. It was likewise important for him to fix dates of discoveries and inventions, aiming to 'titrate' the great civilizations one against another and to find out and give credit where credit was due. In many cases where Needham and his collaborators were able to ascertain an earlier date of a discovery or invention in China than in the West, he concluded that this must have been a case of direct borrowing, indirect transmission, or diffusion stimulus, even if no other concrete evidence was available. Basically, he shifted the onus of proof onto those people who doubted that such a transfer had taken place. Generally speaking, however, Needham was never thinking in simplistic terms, as he did, for instance, admit the possibility of independent discoveries and inventions. From very early on he concluded that until the Scientific Revolution in the late Renaissance the West was not only deeply influenced in the field of technology by Chinese or East Asian technological inventions and scientific discoveries, but also deeply affected by them in its social structure. For instance, the adoption in the West of the Chinese invention of gunpowder and firearms dealt a fatal blow to castles and hence to Western military aristocratic feudalism.

Needham drew a clear distinction between modern science on the one hand and ancient and medieval sciences on the other. Modern science, as it developed only in Western Europe at the time of Galileo, is based on five fundamental characteristics, namely: the application of mathematical hypotheses to Nature, the full understanding and use of the experimental method, the distinction between primary and secondary qualities, the geometrization of space, and the acceptance of a mechanical model of reality. Primitive and medieval sciences distinguish themselves clearly from the modern type, as, for instance, their intrinsic and essential vagueness always made them incapable of proof or disproof. As far as numerical figures entered into them, these numbers were manipulated in forms of numerology or number-mysticism constructed *a priori*, and not employed as the stuff of quantitative measurements compared *a posteriori*.

During his years of study and research in Cambridge, Needham's worldview was characterized by four conceptual clusters that substantially influenced his work for SCC:

1. Needham had a strong antipathy against the mechanical concepts upheld by many physicists of his time. His philosophy of science was influenced by Whitehead's organicism. He was, however, not a rigid defender of Neo-vitalism, but together with Lancelot Hogben argued for its 'mechanical' or 'materialistic' aspects. Needham considered Whitehead's theory of organicism a synthesis of mechanism and vitalism.
2. Needham espoused the idea of evolution as a concept of wide application. For him evolution was not only a phenomenon of the biological order, but could also be observed in social organization. Social organizations necessarily followed a linear course of evolution, for which the Marxist stage theory of social development was an indispensable explanative tool. Social development cannot be explained by biological theory, but needs its own unique approach. Needham's concept of evolutionary development of social organizations did, however, not deal with a socio-Darwinist 'survival of the fittest,' but aimed at overcoming the excesses of capitalism. 'Collectivism,' as it would manifest itself in a worldwide communist society, was seen by Needham as the next higher stage of social organization.
3. Needham sympathized with Marxist dialectic materialism. Most of the researchers in Hopkins's laboratory were politically left wing. This was typical of many British biologists of the twenties and thirties, like J. B. S. Haldane, J. G. Crowther, and J. D. Bernal. During his youth Needham was impressed by the events of the Russian Revolution. Moreover, in 1925 he read Engels's *Dialektik der Natur* [Dialectics of Nature] which fascinated him. During one of his stays at the Roscoff Marine Biological Station Needham and his wife met Louis Rapkine, a biochemist born in Lithuania who grew up in Canada. Rapkine introduced Needham to the Marxist classics. Moreover, he learned much of him

about the living conditions of the lower strata of the working society for which Needham had always entertained great sympathy. Like Julian Huxley and the adherents of a 'scientific humanism,' Needham expanded his interests from biological problems into the social field. Due to his rational, antireductionist attitude toward science, he was convinced that scientists also had social and ethical responsibilities. Democratic, socialist, and populist elements were the main constituents of his political stance. Needham, however, did not count himself an orthodox Marxist because he was not dogmatic with regard to the question of which aspects of human action constituted foundation or superstructure. He belonged to a generation of the 1920s who adhered to Marxism because of ideology and romantic ideals, in contrast to the generation of the 1930s which was characterized by a more realistic attitude toward politics and tactics. In his later years, Needham never gave up his hopes for the realization of an 'ideal socialism.'

4. Needham stressed synthesis over analysis. It was his basic conviction that dialectic materialism was the synthesis between mechanical materialism and idealism. Religion was for him something that need not be got rid of in favor of materialism, but which should be absorbed by it. On the one hand, he stated in 1936 that communism possessed a higher sense of the numinous than any of the traditional religions, and that, on a higher stage, a synthesis has to be carried out between religion and Marxism. Communism could provide the moral theology of our time. On the other hand, Christianity was necessary for him to help redeem the ruthlessness of science. In an autobiographical account published in 1973 under the pseudonym 'Holorenshaw,' Needham informed the public about three antitheses which had determined his life. The first is the antithesis between deep religiousness and science, the second between deep religiousness and his sympathy for socialism, especially in its Marxist form, and the third referring to the differences between Eastern and Western cultures. He declared it to be his duty to transform these antitheses into syntheses. This also shows that Needham was not an adherent of scientism. He was of the opinion that different molds of human experience (e.g., religion, art, history, philosophy, and science) coexist and all have claims for validity, and that science could not do without ethics.

During their tracing of the history of discoveries and inventions Needham and his collaborators unearthed an impressive array of early Chinese achievements in technology and science. One example is the mastery of cast iron in China, a millennium and a half before it was known in the West. This Chinese expertise which started in the fourth century BC and which required substantial empirical knowledge of the properties of iron was based on a highly developed bronze casting technology. Cast iron was not only mass-produced for weapons, agricultural tools, and cooking utensils, but also put to such innovative uses as chain suspension bridges (first century AD) and deep-drilling for brine (eleventh century AD) and, later, natural gas. The double-acting piston bellows producing a constant flow of air both during the pushing and pulling of the piston was probably a crucial device enabling the Chinese to achieve superiority in metallurgy for so many hundreds of years. In metallurgical processing also the crank and the piston rod were developed. In agriculture, row cultivation and intensive hoeing were adopted from about the sixth century BC. By the third century BC frame-plows were equipped with cast-iron plowshares and moldboards which substantially reduced friction and allowed the cultivation of heavy and waterlogged soils. These plows were far in advance to the ards used in the Western world.

About the same time, the equine breast-strap and collar harnesses emerged by which the efficiency of animal power was improved. Other agricultural innovations adopted centuries prior to the West included various types of rotary-fan winnowing machines for the efficient separation of grain and chaff as well as multitube seed drills especially in row cultivation. Both these technical devices were known since the second century AD. All these inventions spurred agricultural production and provided the economic basis for social differentiation and state building.

Among the nautical innovations of the Chinese, apart from the well-known compass, the sternpost rudder (first century AD) and watertight compartments in ships (second century AD) should be mentioned. The Chinese were also great masters in the building of irrigation works, canals, and canal pound-locks. Some of these ancient infrastructure achievements can still be admired today, like the Dujiangyan irrigation system north of Chengdu in Sichuan Province built in the third century BC. Some of these feats of engineering, however, fell into disuse and were forgotten, like the modern-type canal pound-locks with two gates of the tenth century, which were later replaced by the much more ordinary flash-gates with one gate only.

In the military field, Needham noted that gunpowder had arisen from the investigations of Taoist alchemists in about AD 850. About two centuries later it was used for fireworks, bombs, grenades, land mines, and sea mines. In the eleventh and twelfth centuries gunpowder served the production of rockets, and only about a century later it provided the propelling force in guns, cannons, and mortars. In China, however, gunpowder and firearms were not further developed to occupy a position as dominant as that which they did later in European warfare.

Woodblock printing on paper and silk arose in China around the seventh century AD. This allowed the mass production of all kinds of scriptures and texts. However, only few experiments were made with movable-type printing. Paper, another revolutionary product, was invented in China already in about the first century BC. It spread from China to Korea and Japan in the seventh century and to Central Asia, the Arabs and Europe one century later. Another famous Chinese invention that in the eighteenth century was imitated in the West was porcelain.

The decimal system was already in use in archaic China. It also seems that the Chinese were the first to use a blank space for zero and to recognize and use negative numbers as well as decimal fractions. They were also in the possession of a refined value for *pi* (third century AD) and were the first to note the hexagonal structure of snowflakes (second century BC), to mention only the most important inventions and discoveries. Many of the Chinese findings described by Needham and his collaborators in SCC have stood the test of time and thus have to be considered historical facts.

Assessment and Impact

Needham's work in the framework of SCC was frequently the object of criticism that can be summarized as follows: because Needham took modern science in its final result as a guideline, there is a tendency in his work to highlight those Chinese developments and events best suited to be interpreted as antecedents to modern science. Those currents, however, which did not show universalistic characteristics were neglected by him or even considered obstructive to the development of modern science, without his having undertaken a serious attempt at interpreting them as culturally specific and integral systems of thought and action. It has been pointed out that in his earlier works his linguistic capabilities were not of the highest standard, sometimes reading modern scientific ideas and virtues into traditional Chinese texts. Some reproached him for not having differentiated clearly enough between science and technology, because he sometimes regarded technology as nothing more than applied science. Clear conceptual differentiation was also lacking with regard to such concepts as the Scientific Revolution and the Industrial Revolution, as well as invention and innovation.

Others criticized the encyclopedic structure of SCC. The first volumes, at least, were said to be largely characterized by a timeless, even static, sense of history, to provide only a blurred picture of the world of thought and social interaction in the fields of science and technology, and to be inadequate in pointing out temporal and spatial differences. Discussions arose also with regard to individual findings of Needham. This in particular concerned his history of traditional Chinese astronomical clockworks and their linkwork escapement mechanism that he interpreted as the missing link in the development from clepsydras to mechanical clocks, the production of crystalline synthetic sexual hormones from the urine of pubescent boys by Chinese alchemists, or his identification of traditional Chinese concepts of Nature as precursors of Whitehead's organicist view. Moreover, it was shown that cross- and intracultural transmissions of ideas and devices may have been more complex processes than imagined by Needham.

More fundamental criticism addressed Needham's explanations of the socioeconomic and political reasons why the Scientific Revolution did not take place in China. Nathan Sivin repudiated this as an inadmissible contrafactual question that would diminish in interest as soon as it became clear in which social, economic, political, and cultural environments, and for which purposes traditional Chinese scientists carried out their activities. Benjamin Nelson stated that Needham had underestimated the complexity of social, political, cultural, and intellectual processes leading to the Scientific Revolution in the West. Needham's juxtaposition of Europe's mercantile bourgeoisie and commercial capitalism as conducive to the rise of modern science and China's Confucian 'feudal bureaucracy' as obstructive was considered by many critics as simplistic – as was his characterization of the Taoists as promoters of science and the Confucians as exerting a rather negative influence on it. In conclusion, Needham's work is often considered to be a mixture consisting to a large part of solid findings, plausible, but not always incontestable interpretations, personal speculations, and, sometimes, errors.

In spite of these criticisms, Needham's work undoubtedly embodies a number of tremendous achievements. First of all, due to his work not only is much more now known about the history of science, technology, and medicine in China, but it also triggered a dramatic increase in the research activities and institutionalization of the academic disciplines concerned. At the same time, a specialization took place, as it is hardly possible anymore for an individual researcher to deal with all the various disciplines to the same depth. Furthermore, as Nelson pointed out, Needham was much more interested in historical processes than Max Weber, one of the great scholars who had attempted to explain the uniqueness of the Western rise of modern science. Needham's work also underlines the importance of intercivilizational encounters and points to the inevitable drive toward universality and thus the overcoming of all local particularities. This is another difference to Weber who was much more interested in a differential typology and the establishment of ideal types, and thus more or less treated each civilization as a discrete unit. These and other insights of Needham therefore provide important elements for a comparative historical and differential sociology of civilizational complexes and intercivilizational encounters (Nelson, 1986). And although much criticism was voiced against his notion of the universality of modern science because potentially this might be invoked to justify a blanket modernization, one should not forget that Needham not only ascribed social values to this notion, but also perceived it as a sharp tool of critique directed against Eurocentric internalism.

Needs Assessment

James W Altschuld, The Ohio State University, Columbus, OH, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The goal of this article is to describe in a straightforward manner what needs are and their assessment. It begins with a brief overview of the nature of needs and the process for determining them. Then, it deals with origins of the concept, the modern history of needs assessment, definitions, some guiding models for working with needs along with a discussion of their key premises, and a look at commonly utilized methods. It also covers topics such as why needs should be determined, their importance for meaningful program development and improvement, factors affecting the implementation of assessments, and what the future might hold for this area of endeavor.

Origins

Social scientists have a sense of what needs are and what needs assessment is; yet surveys of the training of evaluators who often deal with such entities indicate that relevant coursework is just not there. The implication seems to be that just knowledge of methods is required to do one. The premise of this article is that there is a rich and established base of literature, which makes for more sophisticated practice. A brief look at the history of needs assessment is given followed by definitions of terms, structures to guide assessment, some key issues, and what might be on the horizon for the enterprise.

Where did the concept come from, where did it originate? Wedman (in press) speculated that it was in the Stone Age when our ancestors dealt with the determination of needs. There are no records to support this view but at a later time the Egyptian *Book of the Dead* (British Museum, 2011) talks about what the deceased would require in the afterlife. The proposition that needs are embedded in human existence was demonstrated in Hansen's classic 1991 study. He noted that across fields when people work on problems or issues they think of discrepancies between what is and what should be, that is they start with needs as a foundation for their work.

Recently Atschuld and Watkins (2014) developed a time line of what has taken place since the 1960s until the present as shown in **Table 1**. Several entries in the table should be highlighted. One is that writings about needs and how to identify and use them have been there for years and have accelerated since 2010 although research studies are less in evidence. There is a strong tie between evaluation and needs assessment as exemplified in the writings of Stufflebeam, Scriven, and Roth, and others, and by the national needs assessment group of the American Evaluation Association. Pointed criticisms began in the 1970s, periodically reemerged, and rose to a bit of a crescendo by the early 1990s. Toward the end of the decade and up to the present a new phase of practice has been noticeable, that of a hybrid between asset/capacity building and needs assessment with some major cases appearing.

Definition and Some Concepts

There is a basic idea that underlies all thinking about needs. It is of a discrepancy between what is (current condition) and what should be or what is desirable and that the gap is important in regard to program planning and evaluation. Yet, that simple definition can mask complexities, e.g., there are many ways to define the 'what should be' condition such as what is likely, what is feasible, what is ideal, and so forth. In the field of Human Performance Technology (more in the business and private sectors) 'what should be' might be cast as a high level of performance of an individual or group against lower levels that are observed. Yet, no matter the discipline, deficits are to be identified, examined, and if of high priority they are to be rectified.

The definition requires that current and desired states be measured. That is important for in the past-published studies labeled as needs assessments did not always contain data on both conditions. Since the early 2000s there has been movement toward more appropriate recognition of the components of need. Things subsumed under the definition are different types of needs and the virtually hidden notion of the counterfactual state.

The types of needs would include short- and long-term needs, maintenance needs of equipment and skills, severe versus slight needs, and others. Consider that power blackouts routinely occur in some cities – the value of maintenance takes on meaning. Or think of three levels of need (1 – recipients of service, 2 – providers of service, 3 – the support system that enables level 2 to assist level 1) and it is apparent that the idea of a discrepancy or gap is a rubric for a much more sublime tapestry. Add into the mix the counterfactual state that asks what would happen if nothing were done about a discrepancy. Might it resolve over time of its own accord? A sprained ankle will tend to go away perhaps after several weeks and no direct intervention is needed, although for professional athletes alacrity would be pertinent. So needs have to be prioritized to see if they warrant immediate or longer-term action and the expenditure of resources (money, organizational effort) to improve the situation. In some instances the answer might be no. With the basic premise in hand what are models for assessing need?

Some Guiding Models

Two approaches are well known. The three-phase model of assessment originally sketched out by Witkin in 1984 and in its latest incarnation by Altschuld and Kumar in 2010 is portrayed in **Table 2**.

Table 1 Overview of modern needs assessment (NA)

Time period	*Nature of event(s)*	*Some contributors*
Mid-1960s (the early years)	Elementary and Secondary Education Act (ESEA) of 1965 called for the determination of needs for programs and projects Context, Input, Product, and Process (CIPP) evaluation model in 1965	Congress of the United States Stufflebeam develops his CIPP model with the C part related to needs
Mid-1960s into the early 1980s (the formative period)	Many NAs being done especially in public schools Writings and presentations of some prominent authors Prominent criticisms appear	Witkin's nationwide survey of the practices of school districts Warheit et al.'s (1979) book on NA in mental health Kaufman presents on the topic and develops his model Scriven and Roth paper on the Big Bob idea of needs (see below) Kamis catalogs criticisms of NA
1980s through the early 1990s (coming of age but headwinds)	A heyday of watershed events, at least four major books are written and gain wide acceptance Small number of courses devoted to NA at several universities Small national NA group joins American Evaluation Association (AEA) Criticisms again toward the latter part of the period	Witkin, Kaufman, Neuber, Lauffer, McKillip books on aspects of needs Courses at Southern Illinois, Utah State, and Ohio State The models of Witkin and Kaufman take full form Kaufman publishes numerous papers
Early 1990s through the early 2000s (enhancements but challenges)	Rejoinders to criticisms Attack on NA from an asset/capacity building stance Asset/capacity building efforts take off based on starting from the positive as opposed to a needs, discrepancy-oriented position Major new books on NA are published	Witkin takes on the critics Kretzmann and McKnight (1993) harshly point to the negatives of assessment Altschuld and Witkin partner for two books, Gupta generates one oriented toward business settings Kaufman continues to publish Scriven and Roth paper reissued by the American Evaluation Association
Early 2000s through nearly the end of the decade (continued work and improvement)	Major papers about the placement of NA in organizations, Performance Pyramid, and NA and Evaluation survey Persistence of NA-Topical Interest Group at AEA as a viable entity Hybrid NA and asset/capacity building efforts appear More books about NA	See papers by Altschuld, Wedman and Watkins, Watkins and Guerra Good source on hybrid thinking for asset/capacity building and NA is the CADISPA website The five volume Needs Assessment Kit (Altschuld et al.) and book by Gupta et al.
2010 to the present (toward maturity)	More books, applications in international venues More examples of hybrid assessment in the literature	Gupta, Sleezer, and Russ-eft revise their earlier text, Watkins et al. (2012), Kaufman and Guerra-Lopez (2013), Altschuld (2014)

Adapted from Altschuld, J.W., Watkins, R. Needs Assessment: Trends and toward the Future. New Directions for Evaluation, in process.

Another widely used model is that of Kaufman (Kaufman and Guerra-Lopez, 2013). The first author has proposed that there are sequenced dimensions of needs and one works from the highest down to the lowest in organizations, businesses, and institutions. First are Mega needs, those of the society denoted by a healthy population, more production than consumption, and citizens who are employed and have the skills necessary to be successful in their work. This is necessary for a productive society. From there, needs assessors would progress to the Macro dimension which in education would consist of graduates with the prerequisite skills and understandings for job performance or societal involvement. Finally at the lowest level (Micro) needs assessors would determine if the resources, educational personnel, instructional materials, and so forth are there to satisfy macro needs and in turn would lead to the mega needs being resolved.

Kaufman's approach is based heavily on gaps at each step of the sequence which in essence is an interconnected system. In contrast, Witkin's original three phases are about the process of doing an assessment. No matter which approach is used there will be some overlap across the two frameworks.

Methods for Assessing Needs

In 1995, Witkin and Altschuld described more than 20 methods in categories aligned with the three phases; similarly Watkins et al. (2012) described in some detail numerous techniques employed in needs assessment. Assigning exactly where they fit in the conduct of an individual assessment is difficult because of highly varied use when studies of needs are done. A closer examination of procedures suggests a set of common methods. They are often employed in a complementary manner with the use of several in conjunction with each other as the recommended course of action. Most often quantitative and qualitative strategies are paired, with reliance on a single strategy generally to be avoided.

Table 2 The three phases of Needs Assessment (NA)

Phase	*Nature*	*Methods overview*
Phase 1 – pre-assessment	Reconnaissance to see what needs are there and of sufficient importance be pursued further Usually done under the aegis of an organization or community via a Needs Assessment Committee (NAC) The phase relies mainly on existing sources before going to the expensive, time consuming Phase 2 Phase 1 leads to the decisions to ● do nothing, needs are not really there ● go to Phase 2 entailing more extensive data collection, or ● go to Phase 3, action plans to resolve the needs uncovered	Data in records Databases Information from the literature Information routinely kept internally or by external agencies Evaluation reports if available Other reports Informal interviews Observations Additional methods as appropriate
Phase 2 – assessment	If Phase 1 did not provide enough understanding about needs, enter Phase 2 Intensified data collection via in-depth surveying, full analyses of existing sources, seeking more information, and more exploration of the literature Also might prioritize and causally analyze needs to identify potential solution strategies Decisions are to go no further or enough has been learned and prioritized to plan and initiate solutions (Phase 3)	Formal surveying Individual and focus group interviews More literature review about needs and solutions Causal analyses Prioritization strategies Other procedures
Phase 3 – post-assessment	From what was learned in Phases 1 and 2, begin actions to rectify needs Phase 3 overlaps with the latter part of Phase 2 Develop and implement action plans as well as evaluate how well they were working Lastly, include strategies for evaluating the needs assessment itself	Many of the procedures indicated above especially causal analyses and prioritization Action plan-related activities such as benchmarking, multiattribute utility theory, etc. Formative and summative evaluation procedures

Procedures commonly observed are surveys, epidemiology or database studies, and focus groups or individual interviews. Surveys for needs are unique in that they employ, double or triple scales with the former being more notable. As an example, respondents are asked to indicate the importance of a topic, the extent to which it is being achieved or attained, and, on occasion, the frequency of its occurrence. If triple scaled, a need would be an item that is rated high in importance, low in achievement, and as frequently occurring. Five point (Likert) ratings scales are most prevalent and sometimes there are response categories such as don't know (DK) or not applicable (NA). When the latter are chosen they indicate that the respondents do not have much knowledge about a topic.

Epidemiology as a way to study diseases or other issues is almost a perfect fit with needs assessment in its focus on the prevalence (present time occurrence) of a disease and incidence (what will happen if it spreads unchecked) and the gap between the two conditions. This aligns with the definition of need. The AIDs epidemic in the 1980s is an illustration of epidemiology and the investigative work it entails. What was causing the affliction, was a specific segment of the population being affected, what is its progression, and where did it originate were elements of what had to be studied to determine what must be done to stem the progression of the disease. Fortunately, those looking into the situation were able to identify causes, and (although sadly many were lost early to the ravages of the scourge) their efforts paved the way for helpful drug therapies. Another example would be what is the current rate of retirement of teachers and what might that rate be if the pension system were to include more incentives for leaving the workforce?

Epidemiology almost seamlessly blends qualitative and quantitative methodology and is aligned with current needs assessment practice. Hard data are absolutely essential as an indicator of a problem and its rapid escalation, otherwise the researchers would be lost. That data by itself is insufficient to find out about other aspects of what was happening or is likely to happen. Direct contact via intensive interviews with the infected population or those having the potential of contracting a disease is critical in the process. It is equivalent to what police do on a crime scene when they perform a canvas of the immediate area. This is time consuming and requires extensive resources but there is no substitute for the activity.

Notice that interviews are used. Indeed that is one of the key methods that are part of the needs assessment process, either focus group or individual interviews. What are groups thinking about, what might be the issues on their minds, do others in the group have similar or different views, and so forth. Individual interviews might be done with key informants, those that know the pulse beat of a community or organization. What can they tell us about community views in an in-depth questioning session, and if patterns emerge across responses, can be quite informative and cost effective as compared to large-scale surveys of communities.

Another version of the procedure is rapid or community-based appraisal. Members of a community are recruited and trained to conduct quick and short interviews of a convenience sample in the locality. If there are 10 'interviewers' each doing 10–15 rapid interviews, much can be gained in a short period of time. Community members are often easily trained for the task and is much cheaper due to the substitution for more expensive professional personnel. There may be some loss of quality but not that much in what is derived from the procedure, and there is a positive compensating dimension in the rapport between those providing perceptions and those collecting them. The use of this approach applies both to urban and rural settings.

Before leaving this topic, several other methods merit comment. Many times numerous important needs will be identified but attending to all of them will extend and exhaust resources beyond the breaking point. Priorities must be established and the causes of discrepancies understood. Assessors must be familiar with how to set priorities (not all needs require immediate attention and are of equal importance and meaning to decision-making groups). Causal analysis is imperative to look into the nature of what factors have led to the need. Such activities take place in Phase 2 of the process or early in Phase 3 and will be briefly addressed in the next section.

Table 3 Reasons for doing a Needs Assessment (NA)

Reason	*Explanation*
Human nature	It is how we conceptualize and attack problems It is just part of what we do as people
Systematic strategy for planning based on needs	Requires identification of needs, prioritizing them, analyzing their causes, and determining possible ways to improve predicated on causes It makes sense as a way to move forward
Establishing the basis for formative evaluation of selected solution(s)	Understanding causes leads to better solutions being implemented and where to direct formative evaluation resources May indicate where a solution will most likely fail Leads to a targeted and more selective strategy for rectifying needs
Overall improved program accountability	If the above activities are done well, they help to uncover quality solutions and make for meaningfully being able to demonstrate accountability Adds an enhanced level of sophistication to what we do

Why Is It Important to Deal with Needs?

Now that it has been established what the needs assessment is, why should we be concerned with the whole idea, what is the rationale for doing one (see Table 3)? Hansen (1991) explored, what people do when attacking an issue, a problem, or a concern, and found that despite differences in terminology across fields and contexts there was a core strategy revolving around what is and what should be, and the discrepancy between them which is the very heart of what a need is. The consideration of needs is inherent in planning and human exploration of how to proceed. Therefore one reason is our human makeup and what writers about the topic have simply created a reconstructed logic of what the process is like (see Table 3).

A systematic way to think about planning is the second reason that needs assessment is important. It means that the assessors have thoroughly (not superficially) investigated the topic of concern. They have identified and prioritized needs of most importance for a group, organization, agency, or business to focus on and to which resources should be devoted. It shows dedication to detailed probing of the problem or issue. And if causal analysis has occurred it is likely that a better solution will have greater likelihood of being chosen for implementation and it should have enhanced potential for resolving the underlying problem. Overall the solution should be more in tune with the nature of the discrepancy.

The third reason that assessment is important is that since we have learned what causes the problems and how causal factors operate, we anticipate where the process of change and development may tend to fail. This would tip off where to focus and direct formative evaluation efforts and resources given that not everything can be evaluated. If things were not going right we should be able to see them early, not late, in the process of change and take appropriate corrective actions or modifications. This should increase the probability of success.

Collectively the three reasons point to the conclusion that there is an improved chance of producing programs and solution strategies that achieve the goal of resolving needs. This implies higher program accountability. Thus it seems advantageous to always do a needs assessment, though frequently that is not the case.

What Affects the Implementation of Needs Assessment

Reflect on needs assessment as an exploration of an agency, a community, a company, and so forth. Like a research study, it is very dependent on appropriate conceptualization. But the goal of research is to enhance understanding of phenomena and fundamental propositions about them. Needs assessment is different from research in the use of multiple methods, involving members of the group for which it is done, resulting in change and concrete organizational actions, requiring more of a facilitative stance on the part of the individual or group leading it, and consisting of many steps where it could go awry – lots of things could negatively impact an assessment. Also, depending on the scope of what is being examined (extent and seriousness of the problem, how many people are affected by it), and other factors, needs assessment can be time consuming, expensive to conduct, and usually will end up in resources being directed to one need over another. The latter part of the statement points to how political the

enterprise can be. Someone or some segment of the organization will win and by the same token some will lose.

Focusing so that the endeavor is not so broad that nothing will be accomplished, or so narrow that the bigger picture is missed, is also an important feature. Needs assessment is a bit of an art and thinking through how to start is glossed over in practice, resulting in less than stellar results. More attention should be paid to how to proceed in what can be a complex undertaking so that meaningful outcomes are achieved. Refer back to Table 2 and note Phase 1, see it as the make or break point for success. Has the heart beat of the community or agency been uncovered? Is the assessment dealing with issues that a community values and would the assessment lead to careful thought being given to outcomes? Are the variables examined or to be examined attuned to the group, and would the group be interested in what has been found? If questions like these are not dealt with at the beginning, the probability of change tends to decrease.

This relates to another concern, short-term assessments are estimated to require about 3 months not including getting the solution strategy off the ground. Major needs will take perhaps a year for study or even longer before a solution is in place. In the latter case and with the involvement of a NAC it can be anticipated that maturation (getting bored, losing patience, tiring of the endeavor), as a Campbell and Stanley source of invalidity will arise. If the imagination of the NAC is not captured, motivation probably will deteriorate. Most groups are action oriented and with time-consuming ventures they may become impatient. Extra effort will be necessary to keep the group involved and there is not enough discussion in the literature about maintaining interest and facilitating a work-oriented group (see Spaeth et al., 2013). These are the ingredients that produce a savory dish instead of one that nobody wants to eat.

Other factors affecting the quality of a needs assessment are double- or triple-scaled instruments and multiple methods/sources of data. What on the surface appears to be a simple proposition is not. Altschuld and Hamann (2012) identified problems in wording, prioritizing needs, improper analyses, not fully understanding response options, and so on. Add in that we might want to ascertain the risks inherent in meeting needs or not doing anything about them (that counterfactual state). If not attended to, might risk dissipate and no action is required? Are they really worthy of the investment of time and resources?

Compounding the process is that assessors should employ multiple methods consisting of existing records and databases, interviews, observations, surveys, and group processes, and the difficulty of the task magnifies exponentially. Do assessors have the requisite skills and understandings of diverse techniques? Are they equally adept at all of them? Even if they are, do they have experience in pulling the data collected into a comprehensive summary that integrates findings? What if the results do not agree or in the extreme are contradictory? What approaches guide those doing the work in establishing priorities from such an array of sources? How should they engage with community-based committees to guide them in decision-making?

These concerns are not easy to deal with, but on the other hand they are the excitement of needs assessment. They raise the possibilities for research into the process and for ways to move our work with needs to a higher level. Offering them here sensitizes those doing the assessment to the subtle aspects of needs and the in-depth thought they require.

What of the Future for Needs Assessment

Technology and methodology is evolving. Recently the author ran across a study on health being conducted in the US in which approximately 1 000 000 individuals were given simple I-pad devices to record daily readings on their health. This might appear expensive due to the costs of the devices and for respondent involvement, but putting it in perspective it would produce vast amounts of information that would likely generalize to the entire population and quickly lead to an amazing database readily available for study. The costs, while not unnoticeable, would be relatively small for being able to extrapolate to in excess of 300 000 000 people. Earlier and not so advanced versions of such studies, but still expensive ones, were the Epidemiological Catchment Study of the 1980s, the West of Scotland Study (WOSCOPs), and NHANES (Centers for Disease Control) which is an ongoing investigation of children's health and well-being.

Consider the Geographic Information Systems (GISs) and smartphone/table applications (app) that are now available. The author's son and his family were planning a vacation and found a book about the intended destination that offered an app about recreational sites for an additional eight dollars. It included ties to the GPS so they could easily navigate their travel. If a group was thinking about solutions to their needs that included recreational opportunities, this was a godsend and due to changes in technology it was at their fingertips for a nominal cost. Another advancement is the GIS that Hites et al. (2013) creatively used in conjunction with a qualitative technique (focus group interviews, FGIs) to investigate needs about crime in the vicinity of a large university in a major southern city. They included database information and across sources were able to present concrete portrayals of day- and night-time problems. Aside from the FGIs the other information already existed and simply had to be extracted from such sources.

Yet a different technique is photovoice that has been part of a number of studies. It was used in two ways to uncover needs and/or assets in a community. Inexpensive cameras (cell phones would now be even better) are provided to members of a community or organization and they, with some limited guidance, go out and photograph exemplars of problems, assets (strengths), or both. Once this is done they are assisted in writing descriptions of their photos and the pictures with explanations become the emphasis of discussion in a large meeting involving the broader community. The generation of information and its interpretation are largely under the aegis of the community, not those guiding or facilitating the assessment (the voice of the people is prominent, a concept that has traction in recent work on joint asset/capacity building and needs assessment). It is a very different approach for collecting data and from a perspective perhaps not captured by more traditional investigators or investigations.

Lastly, this text would be remiss if it did not refer to a very sharp challenge to the premise of needs assessment itself.

A counterview emphatically proposed by Kretzmann and McKnight (1993) in their asset-oriented book is that starting with needs is a negative, 'downer,' not an upbeat activity and will not lead to progress, change, and improvement. In the worst case it generates a dependency mindset, particularly for impoverished communities; looking through the needs lens, they will never recognize their strengths and never develop a sense of self-reliance.

A need represents a problem, something that is wrong and we as humans do not plan on that basis. Rather we should look to our assets and resources and view them as the building blocks for moving forward. If we focus on what do we bring to the table to a high degree, we can be in control of our own destiny. Whether we adhere to a needs stance or an asset one, there is merit in the criticism of the above two authors. But is it best to begin with strengths or needs (a rhetorical question if there ever was one)?

A practical alternative is beginning to be seen in the literature. Since about 2000 hybrid studies are appearing in public health, community development, and other areas. They start with assets and resources that a community or group can tap into and utilize. The positive foundation of assets was abundantly clear to the authors of the pertinent articles and was often directly stated as a governing principle for their investigation.

At the same time the authors were not oblivious to the importance of needs and were aware of the prominent role they play in contemplating new directions and in leading to developments that enhance the community or organization. Such hybrid studies are more complex than a stand-alone needs assessment or an asset/capacity building effort and will take considerable time. That is reasonable given issues such as crime prevention, poverty, gun control, health of groups, agricultural services, etc. It is in such contexts that the hybrids are seen. In other words the time and resources to do both and pull together more complicated data is justified because of the complexity of the underlying problems. We cannot and should not expect easy solutions to long-standing social issues; joint asset/capacity building and needs assessment endeavors are a meaningful and reasonable way to proceed.

Summary

What has been provided is an overview of a deceptively simple concept that masks what lies beneath the surface. There are many variations in meaning and ways to frame ideas about needs, and how to assess them so the picture quickly becomes cloudy and the vision gets blurry. Therefore it is to be stressed to keep discrepancy foremost when thinking about needs and that they are fundamental aspects of human activity whether that has been stated or is tacit.

Implicitly, needs are at the heart of everything we do but it is important to distinguish those for individuals from those of organizations, agencies, businesses, government, and the like. This article is about the latter and that opens the door to a myriad of questions such as how are needs determined across multiple groups in different organizations and settings (multifaceted businesses, state and local agencies, and school systems). What happens when perspectives do not coalesce (often they will not) and how can differences be reconciled? What should we do with many important needs that are all competing for finite and precious resources? How are decisions made as to which ones are attended to and which are not?

This is the deeper subtle side of assessing needs. This makes it exciting and a challenge. It is not a cut-and-dried cookie-cutter approach – follow the steps in the process and the needs will be identified and rectified. Every context has uniqueness, so a general approach is fine but must be tempered and tailored to specific nuances and parameters. This makes the assessment of needs more of an art where one has to navigate rough waters and many turns and twists along the way. The assessor must be ever vigilant to constantly changing dimensions. It is never dull.

That being said, the goal was not to deter you from dealing with how needs are assessed and resolved. Rather it was to identify issues and concerns about the journey so that you will be attuned to the hazards that likely will be encountered. The hope is that it has whetted your appetite for digging more deeply into the topic. Many references have been given as guideposts as you begin on your way.

Abstract

Negation refers to a kind of meaning, most intuitively paraphrased in terms of a speaker denying or contradicting something. This article deals with several aspects of negation from a typological point of view. It discusses the meaning and the form of negation. It distinguishes between scope and focus in the meaning section and contrariness and contradiction. The article also offers an overview of some different strategies for expressing negation across languages.

Meaning and Form

The term 'negation' refers to a kind of meaning, most intuitively paraphrased in terms of a speaker denying or contradicting something.

(1) The King of France is *not* bald.

If one has any occasion to use sentence (1), one will use it to deny or to contradict the view that the King of France is bald. One communicates this negative meaning with a linguistic sign, viz., with the word *not*. This word can be called a 'negation,' a 'negative marker/adverb/particle' or a 'negator.' Obviously, the meaning and the form are related: one could say that the English word *not* is dedicated to the expression of a negative meaning. However, the dedication is not complete. Not every use of a negative marker actually conveys a negative meaning.

(2) Je crains que Jean *ne* vienne.
I fear that Jean NEG come.SUBJ.PRS.3SG
'I fear that John is coming.'

In French (2), the complement of a verb of fearing may contain the negative element *ne*, but what the speaker fears in (2) is not that John would not be coming, but rather that he would. Conversely, not every transmission of a negative meaning needs a unique dedicated negative marker. In (3) the same negative meaning allows two strategies, and neither is more dedicated than the other.

(3) (a) I saw *nothing*.
(b) I did*n't* see *anything*.

In what follows the focus will first be on meaning, and then on form. In the section on form, some attention will also go to the diachrony of negation. A more extensive, recent, multiauthored discussion of negation is Horn (ed.) (2010).

Meaning

Scope and Focus

In this section, we differentiate between the scope and the focus of negation. Negation can have scope over a number of constituents or over just one constituent. In Shakespeare's *Julius Caesar*, Brutus has to explain to the citizens of Rome why he killed Caesar. His speech includes the following words:

(4) Not that I loved Caesar less …

Sentence (4) starts with the negator *not* and is said to be 'within the scope of negation.' It is a statement that some citizens of Rome might have made in the context of Brutus' murder of Caesar: if one murders someone, one probably does not care for the victim too much. We here hit upon a typical feature of negation: when a proposition is negated, it is usually entertained in the context.

Note that though *not* has scope over an entire sentence, the negation does not really concern each constituent of the

sentence. What is denied is only the degree of Brutus' love of Caesar, compared to his love of Rome. For this more restricted sense of aboutness, one often uses the term 'focus' of the negation, and so in (4) the focus is the degree of Brutus' love and this aboutness is not reflected in the syntax. In (4) the syntax is simply vague with respect to the focus of the negation. Even when we integrate the negation into the sentence, as in (5), the focus may still be syntactically vague.

(5) I did not love Caesar less,
  (a) … I loved Rome more
  (b) … Cassius did
  (c) … I loved Antony less

Although in (5) the negation is syntactically associated with the verb, it does not necessarily negate the verb. It remains a 'sentence negation.' This is different in (6), which is part of what Mark Antony has to say to the Romans.

(6) I come to bury Caesar, *not* to praise him.

In (6) the scope is still a whole sentence: Mark Antony denies the truth of the *I came to praise Caesar*. However this time the focus of the negation is much clearer: it is the constituent *to praise Caesar*. This use of the negation can be called 'constituent negation.'

The study of negation and its relation to the truth of the sentence is not only a concern for linguists. It has been on the agenda of logic for as long as the discipline exists. Within logic, one can approach negation from the perspective of scope. One is then necessarily doing propositional logic, whereby negation will be a propositional operator. When one looks at the focus of negation, however, one can enter the internal structure of the proposition and one can enrich the study of quantifiers (*all*, *some*) with the study of negative quantifiers (*not all* or *no*, *not some*). A term for the part of the scopal proposition that is out of the focus of negation is 'presupposition.' The term was introduced into twentieth-century philosophy of language by Strawson (1950). It was a much debated notion in the 1970s and attempts were made to turn it into a pivotal notion in the study of the interface between semantics and pragmatics (e.g., Levinson, 1983). As to pragmatics, note that the quote in (4) is only part of what Brutus said: the full utterance is (7). After identifying the lack of love as the wrong motive for the assassination, Brutus goes on to identify the real motive, viz., the love of Rome.

(7) Not that I loved Caesar less, but that I loved Rome more.

Without the part of the sentence that starts with *but*, the audience would not be satisfied. In general, people are more interested in what is the case than in what is not the case, and in the context at hand, the Romans are more interested in what motivated Brutus to kill Caesar than in what did not motivate him. As compared with positive sentences, negative sentences are marked and relatively infrequent.

Contrariness and Contradiction

(8) (a) Mark Antony was *unhappy*.
  (b) Mark Antony was *not happy*.

In both versions of the sentence in (8) we are arguably dealing with constituent negation: in both the speaker denies the appropriateness of the predicate 'happy.' However, the two versions can differ in meaning. In (8a) Mark Antony is reported as being sad. (8b) is vague: Mark Antony could indeed be unhappy too, but he could also be neither happy nor unhappy, or he could even be 'very happy.' Both 'unhappy' and 'neither happy nor unhappy' are instantiations of 'not happy,' and 'not happy' is called the 'contradictory negation' of 'happy.' On the other hand, 'unhappy' is the 'contrary' negation of 'happy.'

Like the distinction between sentence negation and constituent negation, the one between contradiction and contrariness exists since the beginnings of logic, most prominently since the formulation of the Aristotelian 'Square of Oppositions,' implicit in Aristotle but explicit first in the work of the Apuleius of Madaura (second century BC, Londey and Johanson, 1987). A version of this square, as applied to quantifiers, is shown in Figure 1.

Just like 'unhappy' is the contrary of 'happy,' 'all not' is the contrary of 'all,' and just like 'not happy' and 'happy' exhaust all logical possibilities and are thus each other's contradictories, so 'not all' and 'all' are contradictories.

Notions such as contrariness and contradictoriness have been a concern to both logicians and linguists. What interests linguists is that these notions offer a framework for the study of lexicalization patterns. Just like English *unhappy* is a lexicalization of the contrary of *happy*, English *all* has its contrary lexicalized as *no*. The contradictory 'not happy' does not allow for a lexicalization, and neither does 'not all.' What these examples illustrate is that contrariness lexicalizes more easily than contradictoriness (at least in English), which is not to say that the latter does not lexicalize at all (thus English *non-*, different from both *un-* and *in-*, often produces contradictories, e.g., *nonscientific*). Linguists have also made it clear that contradictory notions often change their meanings into contrariness. A classic case, known since Tobler (1882), is French *il ne faut pas*. It used to mean 'it is not required,' which is the contradiction of 'it is required,' but it now only means 'it is forbidden,' which is the contrary of 'it is required.' The linguist that has done most for making the logical tradition relevant for the linguistics of negation and for discussing issues of lexicalization and polysemy is Laurence R. Horn (esp. 1989). Horn has also looked at what has come to be known as 'negative raising' from this perspective. What happens with negative raising is that a negation whose meaning is felt to belong to

Figure 1 Aristotelian square – square of oppositions.

a complement clause is actually expressed with the complement taking main verb. Consider (9).

(9) (a) I do*n't* suppose that you believe him.
(b) I suppose that you do*n't* believe him.

Using a transformational perspective, the negation can be seen as 'raised' from the lower clause (*you believe him*) to the higher clause (*I suppose*). The point that is relevant here is that the two versions of the sentence can be characterized in terms of the distinction between contrariness and contradictoriness. The raised (9a) is literally a contradictory negation (either one supposes something or one does not), but it is normally equivalent with the nonraised (9b) and it then conveys a contrary meaning (instead of supposing *p* and supposing *not p*, one could also suppose neither *p* nor *not p*).

Form

Negation can take many forms, both morphological and syntactic, and occupy different positions within the sentence. This section deals with this matter. The distinction between *unhappy* and *not happy*, just touched upon, obviously has a formal dimension too. In *unhappy* the negation is expressed with morphology, more specifically with a prefix. In *not happy* the negative marker is an independent word, an adverb or particle – one can speak about 'syntactic negation.' Semantics and form are related. With *unhappy* versus *not happy*, affixal negation is associated with contrariness, and syntactic negation is associated with contradictoriness. The relation is not very tight, however. The syntactically negated *il ne faut pas que*, after all, expresses a contrary meaning in present-day French. Conversely, in *nonscientific*, the prefixal *non*-strategy results in contradictoriness.

Crosslinguistically, negating with morphology and negating with a separate syntactic element are the two basic strategies. Sound or word order differences may have a function too, but they rarely or never mark negation by themselves. Both morphological and syntactic negation exhibit subtypes. The linguist's increased understanding of the typology of morphological and syntactic negation is directly related to the increased importance of typology in general, in the wake of Greenberg (1966). Important works in the typology of negation are Dahl (1979), Dryer (1988), Forest (1993), Honda (1996), Kahrel (1996), Miestamo (2005) and, somewhat indirectly, Haspelmath (1997). The great variation in the expression of negation, both in one and the same language and across languages, has also been a challenge for formal models of grammar, e.g., in generative grammar (Haegeman, 1995), lexical functional grammar (Knüppel, 2001), or optimality theory (de Swart, 2010).

As to syntactic negation, there are two subtypes: either the negator is an uninflected element (adverb or particle) or it is a verb (and, depending on the criteria used, an auxiliary verb). English *not* is an example of an uninflected element. For an example of a negative verb, one can turn to the Tungusic language, Evenki. Evenki has a negative verb, whose stem is *e-*, which shows agreement with the subject in person and number, and which furthermore inflects for tense, aspect, and mood. It combines with what Nedyalkov (1994) calls the 'fixed form of the negated lexical verb' ('FFNLV').

(10) Si min-e *e-che-s* doldi-ra.
you I-ACC NEG-PST-2SG hear-FFNLV
'You did not hear me.'
(Nedyalkov, 1994: 16)

Negative verb forms are arguably also the English form *don't* as in (11) or the Classical Latin negative imperative construction with *noli* in (12).

(11) I *don't* like reggae.

(12) Noli venire.
'Don't come.'

The Evenki negative verb differs from the English and Latin ones, however, in that a morphological analysis of the latter will allow one to identify a morphological negator, too. The element *don't* contains the morphological (enclitic) negator *n't*, and *noli* is the imperative of the negative *nolle* 'not want,' which is a combination of *velle* and a prefixal (or proclitic) *ne*. This does not detract from the fact that *don't* and *noli* count as syntactic negators. To negate (13) and (14), the morphological negator cannot attach to the main verb, nor can it be replaced by a negative particle.

(13) (a) I like reggae.
(b) *I like*n't* reggae
(c) *I like *not* reggae
(d) *I *not* like reggae.

(14) (a) Veni '
Come!'
(b) **Ne*veni.
(c) **Non* veni.
(d) *Veni *non*.

It has been argued that if a language has a special negative verb, it will frequently be an existential verb or a verb of wanting, and that these specialized constructions may lose their verbal properties, thus turning into particles (Payne, 1985: 222; Croft, 1991). It has also become clear (esp. through Honda, 1996) that when a language employs a special verb to express negation, this special verb does not itself have to be negative. In the Carib language, Hixkaryana, negation can be expressed with an affix on the verb, but this construction further requires a positive copula 'be.'

(15) (a) Koso w-ono-ye
deer 1SBJ/2OBJ-eat-DISTPST
'I ate the deer.'
(b) Koso y-ono-*hra* w-exe-ye.
deer 3-eat-NEG 1-be-DISTPST
'I didn't eat the deer.'
(Derbyshire, 1979: 48)

A literal paraphrase of (15b) is 'I was not/without eating the deer,' and there is a sense in which the sentence is not really negative.

Note that each of the syntactic negators illustrated thus far precedes the main verb. There seems to be a consensus that languages generally prefer to have their negation in front of the main verb, an observation that was perhaps first made by Jespersen (1917: 5), named the 'NEG FIRST' principle by

Horn (1989: 293, 449–452), and found confirmation in large-scale typology in Dahl (1979) and Dryer (1988). However, a postverbal position is by no means rare, as in Dutch (16), or as when negation is sentence-final, i.e., post-everything, and hence also postverbal, e.g., in the Chadic language, Ngizim, in (17).

(16) Ik hou *niet* van reggae.
I hold NEG of Reggae
'I don't like reggae.'

(17) Ii naa duuka *bai*.
I have horse NEG
'I don't have a horse.'
(Thompson, 1998: 328)

Whether the NEG FIRST preference also holds for morphological negation is not clear (for conflicting views see Dahl, 1979: 82 and Bybee, 1985: 177). In any case, morphological negation can be prefixal, already illustrated with Latin *noli* in (12), as well as affixal, as in English *isn't*.

Negation, whether syntactic or morphological, may also involve a part that precedes and a part that follows. This is often called 'discontinuous' or 'embracing' negation. It is illustrated with French (18) and with Cairene Arabic (19) (Bernini and Ramat, 1996: 47).

(18) Je *ne* le lui donne *pas*
I NEG it him give NEG
'I don't give it to him.'

(19) *Ma*-katab-m̄-š.
NEG-write. PFV-3PL-NEG
'They didn't write.'

Discontinuous negation is a special case of double negation. It is particularly perspicuous and well-studied in European languages (Bernini and Ramat, 1996), less so in the languages of Africa (Devos and van der Auwera, 2013) and the Pacific (Vossen and van der Auwera, 2014). The *locus classicus* is Jespersen (1917), and what has come to be known – through Dahl (1979: 88) – as 'Jespersen's cycle', is the view that languages may go from single negation to double negation and then back to single negation. The double negation is usually taken to result from some kind of emphasis, though the pragmatic notion of emphasis is itself not all that clear (Schwenter, 2006; Hansen and Visconti, 2009), after which the new single negation may result from the bleaching of the emphatic meaning. The phenomenon was already described before Jespersen (1917); very clearly so by Meillet (1912), who spoke of this cycle as a 'spiral' and used it to illustrate the more general process of grammaticalization. We now know that the multiple exponence of negation need not be restricted to double negation, for languages sometimes manifest triple and rarely even quadruple negation. Nese, a language of Vanuatu, normally has double, embracing negation, with a realis–irrealis alternation in the preverbal negative prefix, with *se* being for realis and *be* for irrealis, but the two preverbal prefixes can be concatenated, thus filling the first slot twice, and as a result we get three markers.

(20) Nese (Crowley, 2006: 70)
Ø-se-be-yes-*te*
3SG.NEG-NEG-walk-NEG
'(S)he did not walk.'

In Lewo, another Vanuatu language, older speakers may double up their preverbal realis prefixes (*pe*) too, but this time with the particle that is normally postverbal, which may still occur in its usual postverbal place, and there may even be a clause final negation – thus resulting in four negations.

(21) Lewo (Early, 1994: 420)
pe-re a-pim *re* *poli*
NEG-NEG 3SG.come NEG NEG
'They didn't come.'

(21) also shows that multiple exponence may both involve the repetition of a negator (*re*) or the occurrence of more than one different negator (*pe*, *re*, and *noli*). An example of a language that doubles, like French, but through repetition, unlike French, is Afrikaans.

(21) Ek sal *nie* kom *nie*
I shall NEG come NEG
'I won't come.'

Note also that language need not have double negation in the French style to have more than one negation. Quite often languages negate declarative and imperatives with different markers (van der Auwera et al., 2005), and sometimes there is more than one marker for each environment. Mandarin, for instance, has at least three (and arguably five) types of declarative negation, viz., *bu* and *méi* (*yǒu*), and at least two prohibitive negations, viz., *bié* or *buyào* (Li and Thompson, 1981: 417, 418, 455).

(22) (a) Tā *bu* niàn shū
3SG NEG study book
'(S)he does not study.'
(b) Tā (*méi*)*yǒu* kāi mén.
3SG NEG open door
'(S)he didn't open the door.'
(c) *Bié*/*buyào* dòng!
PROH move
'Don't move!'

The negation of existential, locative, or adjectival predicates also often needs special negations. In Serbian, for example, the normal negation is *ne*, but, at least in the present, in an existential proposition a special negation is used, a univerbation containing the normal negation (Veselinova, 2010: 199–200).

(23) (a) Meri pev-a,
Mary sings
'Mary sings.'
(b) Meri *ne* pev-a.
Mary NEG sings
'Mary does not sing.'
(c) Ima divlj-ih mačak-a
has wild-GEN.M.PL cat- GEN.M.PL
'There are wild cats.'
(d) Nema divlj-ih mačak-a
not-has wild- GEN.M.PL cat- GEN.M.PL
'There aren't any wild cats.'

It has been claimed that special negations of this type may take over from the normal negation and that we thus have

another type of negative cycle, different from Jespersen's cycle (Croft, 1991; Veselinova, 2010).

A rare manifestation of negation, even rarer than quadruple negation is 'zero negation.' In South Dravidian languages, negation can be expressed by the mere absence of a tense suffix. Havyaka Kannada, spoken in the coastal areas of the Indian state of Karnataka, makes a distinction between indicative and subjunctive, and between past and nonpast. In (23a–b) the verbal forms have a tense mood slot filled by the nonpast indicative and subjunctive forms. In (22c) this slot is unfilled, and this in itself marks the structure as negative subjunctive (van der Auwera and Bhat, 1999).

(23) (a) ma:śTrakko kate o:du-tt-avu
teachers story read-IND.NPST-3PL
'The teachers are reading a story.'
(b) ma:śTrakko kate o:du-g-u
teachers story read-SUBJ.NPST-3PL
'The teachers may be reading a story.'
(c) ma:śTrakko kate o:d-Ø-avu
teachers story read-SUBJ.NEG-3PL
'The teachers may not be reading a story.'

Zero negatives may be rare, but they are not exclusive to Dravidian. They have also been reported for the Tupí language Karitiána, spoken in the Amazon Basin. According to Landin (1984), affirmative sentences mark verbs with a preverbal particle or clitic expressing affirmation. In negative sentences, however, there is no prefix or clitic.

(24) (a) Y ta-oty-j ỹn
I AFF-bathe-T I
'I will bathe.'
(b) Y oty ỹn
I bath I
'I will not bathe.'
(Landin, 1984: 237)

A general discussion of this phenomenon is offered by Miestamo (2010).

Note that the verbs in the Karitiána and Havyaka Kannada negative sentences lack tense markers. This touches upon a large area of investigation: the relation between negation and other categories. A forceful illustration of the intricacy of this relation is provided by the Mixtecan language, Copala Trique. The illustration makes the following points: (1) a language may have more than one negative marker, (2) the choice between them may be related to the choice of other categories, in this case a tense-aspect-mood ('TAM') category, and (3) the compositionality of joining the negative marker and the TAM marker need not be very transparent. In (25a) the prefix *g*-marks completive TAM. The language has two negative markers, *ne̥*^{3} and *ze̥*^{4}. The construction in (25a) combines only with *ze̥*^{4}. But then the TAM changes and the negated completive becomes what Hollenbach (1976: 126) calls 'potential.' Note that the superscripts in the examples mark tone contours.

(25) (a) g-ucu̥h^{34} žini^{3} yuwe^{21} âh
COMP-lay boy palm.mat PRT
'The boy laid the palm mat down.'
(b) *ze̥*^{4} g-ucu̥h^{34} žini^{3} yuwe^{21} âh
NEG COMP-lay boy palm.mat PRT
'The boy won't lay the palm mat down.'

To reach the meaning 'The boy didn't lay down the palm mat,' one has to start from a potential aspect.

(25) (c) *ne̥*^{3} g-ucu̥h^{4} žini^{3} yuwe^{21} âh
NEG POT-lay.POT boy palm.mat PRT
'The boy didn't lay the palm mat down.'

Negation may also relate to the shape and the meaning of referring expressions. In Russian, for instance, objects that take Accusative cases in positive environments may allow or prefer Genitive case in negative environments (Timberlake, 1993: 869).

(26) (a) On soxranil podlinnik pis'm-a
he preserved original.ACC letter-GEN
'He preserved the original of the letter.'
(b) On *ne* soxranil podlinnik/ podlinnik-a pis'm-a.
he NEG preserved original.ACC/ original-GEN letter-GEN
'He didn't preserve the original of the letter.'

Or consider English (27): the word *something* is normally replaced by (c) *not ... anything*.

(27) (a) I heard *something*.
(b) ?I didn't hear *something*.
(c) I did*n't* hear *anything*.

That the addition of a negation to a positive utterance may involve changes to other parts of the sentence has been given a typological study by Miestamo (2005). He introduces the concepts of symmetry and asymmetry: when the negation leaves the positive utterance unchanged, the negation is called 'symmetric' and if there is a change, the negation is 'asymmetric.' The specific form of asymmetry illustrated with the switch from *something* to *anything* has received a lot of attention from semanticists. It concerns 'polarity,' both the positive polarity of *something*, which prefers positive contexts, and the negative polarity of *anything*, which prefers either negative context or negative-like contexts, such as questions or conditionals (e.g., van der Wouden, 1997).

(28) Did you hear anything?
(29) If you hear anything, let me know.

The study of what unites negative and negative-like contexts has received various answers, prominent ones being those of Ladusaw (1980) and Giannakidou (1994).

Note that English allows two alternatives to (27c).

(27) (d) I heard *nothing*
(e) I did*n't* hear *nothing*.

In (26d) the indefinite itself is negative – a strategy that seems typical for Europe (Kahrel, 1996; Haspelmath, 1997) and the

Americas (Van Alsenoy and van der Auwera, 2014), and in (26e), which is substandard English, there is both a negative indefinite and a clausal negation. This is a kind of double negation, similar to the one illustrated with French (17), but different enough to deserve its own label, viz., that of 'negative concord.'

Negotiation and Bargaining: Organizational Aspects

This article is reproduced from the previous edition, volume 15, pp. 10473–10477, © 2001, Elsevier Ltd, with an updated Bibliography section supplied by the Editor.

Negotiation and bargaining is a process in which two or more parties seek a mutual agreement through an explicit or implicit exchange of views. The focus of this article is on international negotiation and bargaining with a special emphasis on the role of international institutions in facilitating cooperative bargains. In particular, the article discusses institutional design in connection with the nature of the problem that parties face, viewed through the lens of the provision of different types of goods.

The Diversity of Bargaining Situations

Reaching a mutual agreement may take very different roads depending on the characteristics of the bargaining situation. This section discusses the key distinction between positive verses zero-sum situations. It then relates this basic difference to a typology of goods that parties may seek to provide through a process of negotiation.

Pure Conflicts of Interest: Zero-Sum Situations

A widespread assumption is that bargaining is, foremost, a process in which parties seek to reconcile contradictory interests and values. The aim is to agree on a particular split of the differences between parties. Such situations have been labeled 'zero-sum situations' and are particularly salient when negotiators value outcomes in relative terms. In such cases, any gain by one party comes at the expense of a loss by another party. Bargaining is essentially a process of (re)distribution. In international politics, an archetype of a zero-sum situation is the division of a given territory (for instance, the carving-up of the Antarctic into different national sectors). In economics, the process of allocating market shares under nongrowing market assumptions is also a zero-sum situation.

Mixed-Motive Situations

Whereas distribution is often a key concern of bargaining, parties may also share common interests. Agreements can create value, as well as distribute it. Negotiation situations with both distributive and creative dimensions are labeled 'mixed-motive situations.' Figure 1 illustrates the two dimensions for a hypothetical bargaining case between negotiators Alpha and Beta aiming at establishing market shares.

Moving along the line [1, 1] corresponds to the case of pure conflict of interests mentioned in Section Pure Conflicts of Interest: Zero-Sum Situations. Negotiator Alpha and Beta fully control a steady market and have to mutually agree on a distribution of market shares. Consider, however, the case where Alpha and Beta are not the only market actors and thus will not be able to fully control the market unless they come to a mutual agreement. In Figure 1, point A is the outcome in case of no agreement, with Alpha and Beta joint market shares lower than one. Bargaining aims at reaching total control of the market, thus creating value collectively. The collective gain must be redistributed, along segment [B, C] in Figure 1. Another mixed situation arises when negotiators seek to expand the total size of the market, from 1 to $(1+x)$ in Figure 1. This does not eliminate the initial distributive aspect of bargaining but makes the potential conflict less severe.

In sum, in mixed-motive situations there may be a trade-off between individual and collective rationality. Mixed-motive situations dominate when negotiators not only care about bargaining outcomes in relative terms but also in absolute terms (Bazerman, et al., 2000).

Bargaining Situations and Types of Goods

Bargaining situations may be characterized by different combinations of positive and zero-sum features. In particular, it is useful to distinguish four types of objects or goods that negotiators may deal with, namely public goods, common pool resources (CPRs), inclusive club goods, or private goods (see Aggarwal, 1998; Cornes and Sandler, 1996; Snidal, 1979).

Differences among goods can be characterized along two dimensions: jointness, which refers to the extent to which goods are affected by consumption; and by the possibility of exclusion, which refers to whether noncontributors to the provision of the good can be kept from consuming it (see Table 1).

The two dimensions – jointness and exclusion – largely influence the mixture of interests in a bargaining process. In the case of public goods, there is an important value-creating potential – given that actors can consume the same amount of the good without affecting the consumption of others (as in

Figure 1 A mixed-motive bargaining situation.

Table 1 Type of goods

		Jointness? YES	Jointness? NO
Exclusion possible?	NO	Public	Common pool resources
	YES	Inclusive club	Private

the case of national defense). Yet, the possibility of cost sharing creates a distributive aspect to this good. Given the impossibility of excluding noncontributors, there is in fact a dual distributive problem – among those who pay for the good and between those who pay and those who do not.

Inclusive club goods refer to the case of goods that exhibit jointness (not diminished, by use), but where exclusion is possible (for instance satellite transmission of television). In this situation, bargaining reveals a strong value-creating feature and the problem of distributing costs is less problematic than in the case of public goods because of the possibility of excluding noncontributors from the consumption of the good. The availability of exclusionary mechanisms may help generate revenue, which further reduces the initial problem of cost distribution.

The positive potential of cooperation to collectively produce private goods tends to be complicated by the distributive problem created by the lack of jointness (for instance, the provision of a system of irrigation that delivers private amounts of water to different field owners). Yet, the availability of exclusionary mechanisms can alleviate the problem of distributing the costs. By contrast, in the case of common pool resource goods, bargaining is essentially a distributive process among those that are willing to pay for the good and between them and the noncontributors.

Bargaining Situations and the Role of Institutions

When and how do institutions affect patterns of negotiations? We begin with a definition of institutions, and then turn to an examination of the role they might play. The most readily evident role for institutions could be for situations of market failure, described nicely by the Prisoners' dilemma. In such cases, institutions may help to overcome suboptimality and ensure that actors reach a mutually superior outcome by cooperating. But as noted in Section Institutional Designs for Different Goods, other bargaining situations might also benefit from institutions. Section Bargaining to Create Institutions briefly examines some theories that help explain the bargaining process leading to the formation of institutions themselves.

Definitions: Metaregimes, Regimes, and International Institutions

International institutions have been defined in many ways, and considerable disagreement remains over the differences among international organizations, international institutions, and international regimes. International organizations are generally seen to be more formally specified institutions, with a secretariat, permanent office, and the like. International regimes have been defined as sets of principle, norms, rules, and decisions upon which actors' expectations converge (Krasner, 1983). It is useful to distinguish between principles and norms on the one hand, and rules and procedures on the other. This allows us to delineate two aspects of institutions: metaregimes and regimes (Aggarwal, 1998). Whereas metaregimes represent the principles and norms underlying international arrangements; international regimes refer specifically to rules and procedures. Regimes can be examined in terms of their characteristics: their strength, nature, and scope. Strength refers to the stringency of the multilateral rules that regulate national behavior; nature (in an economic context) refers to the degree of openness promoted by the accord; and scope refers to two aspects: (1) the number of issues incorporated in the regime, or issue scope; and (2) the number of actors involved (bilateral or multilateral), or institutional scope. To summarize, international institutions consist of metaregimes and regimes; if they are highly formalized, we can refer to them as international organizations.

Institutional Designs for Different Goods

Institutions affect the strategies available to actors and the payoffs linked to various bargaining outcomes. Systematic and specific links between bargaining situations and institutions have been explored through strategic analysis of actors' behavior (Aggarwal and Dupont, 1999; for earlier efforts, see Snidal, 1985; Stein, 1982). Aggarwal and Dupont (1999) model negotiation processes over the provision of diverse types of goods with game-theoretic structures that correspond to different assumptions about the costs and benefits of these goods and variation in actors' capabilities. They derive a variety of games (including the situations known as Prisoners' Dilemma, Chicken, Assurance, Harmony, Deadlock, or Battle of the Sexes; for a taxonomy of situations see Rapoport and Guyer, 1966) that can be solved using the Nash equilibrium concept (Nash, 1951). Issues of institutional design are then discussed in connection with the evaluation in terms of efficiency of the predicted outcome(s) of the various games. This analysis yields the following findings on the role of institutions in bargaining situations.

First, institutions may help secure positive outcomes in bargaining processes. When actors have large resources and when they face public and CPR goods, conflict may prevent the provision of such goods. Institutions can play the role of a third party in such cases and enforce a mutual agreement, making the parties more willing to settle on a bargaining outcome in the first place. To successfully overcome the tendency of players to defect, institutions should be strong and formalized. When actors have fewer resources, free riding is less of an option and the problem is one of developing mutual confidence in the ability of the other actors to implement a bargain. In such cases, institutions may provide insurance schemes against defection.

Second, institutions may reduce distributive problems. They may eliminate some sharply asymmetric outcomes and may provide focal point solutions for both cost sharing (which applies to all types of goods) and benefit splitting (when there

is no jointness of supply, that is, for private and CPR goods). Institutions with a firmly and widely established metaregime tend to perform these tasks well.

Third, institutions are not useful only for their help in the initial provision of various types of goods, but also may provide ongoing benefits. For instance, institutions may be useful even if there is some powerful political entrepreneur, or hegemon that provides public goods. Hegemons wish to coerce weaker actors to move away from free riding on the unilateral provision of goods and wish to have them carry some of the burden. They try to do so by linking the provision of the good with other issues. This can be done through institutions that connect different issues.

Fourth, institutions help clarify the mechanism of exclusion (Scott and Davis, 2007). Goods are rarely naturally given but must often be constructed. Actors in international relations use institutions to construct and enforce exclusionary mechanisms. Careful institutional design might, therefore, transform problematic goods such as public or CPR goods into less-problematic bargaining situations such as club goods.

Bargaining to Create Institutions

While institutions may help facilitate or alter the costs and benefits arising from the bargaining process, institutions themselves are the result of a bargaining process. We can consider three schools of thought that have been used to explain the formation of institutions (see Aggarwal, 1998 for references on these three schools of thought). First, from a neorealist power-based tradition, states in the international system compete for security in an anarchic international system. For analysts in this school, international institutions are simply reflections of the existing balance of power, and institutional outcomes have distributional consequences, that is, benefits from cooperation may be unequal.

The neoliberal tradition, on the other hand, emphasizes the incentives that states have to cooperate. In the neoliberal framework, states create 'rules of the game' (i.e., institutions) based on certain agreed-upon norms. Institutions foster sustained cooperation as well as lower information and transaction costs in a particular issue-area. International institutions are seen to be 'sticky' – that is, existing institutions constrain future institutional change – and new institutions must be designed to be either 'nested' within, parallel, or independent from existing institutions (Aggarwal, 1998). Nested institutions are hierarchically ordered. Parallel institutions refer to an institutional division of labor, while independent institutions are simply unconnected since their mandates do not overlap.

The cognitive perspective stresses the role of expert consensus and the interplay of experts and politicians in the formation of institutions. Those within the cognitive tradition are concerned with how the development of knowledge can foster learning on a particular issue area that may drive policy innovation (Hodgkinson, 2003).

Future Research Directions

The issue of institutional design, both at the international and domestic level, will remain a key research and policy challenge for the future. Analysts are increasingly recognizing the need to precisely specify the types of bargaining situations for which institutions might be needed. Rather than debating if institutions are necessary or useless, future work will provide us with a more precise understanding of the nature of goods and their relationship to institutions. Together with insight into the factors that contribute to the creation of institutions themselves, we will achieve a better understanding of the conditions under which institutions facilitate and contribute to the bargaining process.

Abstract

Negotiation is a communication process that lawyers use to resolve disputes and to complete transactions on behalf of their clients. Two models are likely to guide lawyers' negotiations: a distributive model, which posits that negotiation is primarily a zero-sum game; and a problem-solving model, which posits that negotiation is a collaborative search for joint gains. Regardless of the negotiation model(s) employed, lawyer-negotiators find that predictable strategic, psychological, and structural barriers often arise to prevent them from obtaining optimal negotiation outcomes for their clients.

Negotiation is an interactive communication process that occurs whenever we want something from someone else or another person wants something from us (Shell, 1999). Whether functioning as litigators handling civil disputes; as transactional or corporate lawyers putting together deals; as policymakers or advisors proposing and revising rules and regulations; or as prosecutors or defense counsel litigating criminal cases, lawyers negotiate.

Negotiation Models

Scholars have identified two basic models of, or approaches to, negotiation. The first, and perhaps most familiar, is variously labeled the 'adversarial,' 'distributive,' 'positional,' or 'competitive' model of negotiation (Gifford, 1985; Lewicki et al., 1999). This distributive model of negotiation posits that negotiation is a zero-sum game in which any gain one party receives necessarily occurs at the expense of the other party. Because it views negotiation as a zero-sum game, this model counsels negotiators to attempt to claim as many of those gains as possible through the use of such tactics as extreme opening positions, few (and small) concessions, commitments to positions, and the withholding of relevant information (Gifford, 1985). The distributive model, in short, places a primacy on claiming value in negotiation.

The downside to the distributive model, at least according to its critics, is that it is often harmful to the relationship between the parties and can easily lead to impasse or to negotiated agreements that leave value on the table. To address these shortcomings, scholars have developed a second approach to negotiation, currently fashionable in American law schools (as well as in business, public policy, and international relations schools), called the 'problem-solving,' 'integrative,' 'interest-based,' or 'principled' model of negotiation (Fisher and Ury, 1991; Menkel-Meadow, 1984; Walton and McKersie, 1965). The problem-solving model of negotiation posits that negotiation is not necessarily a zero-sum game. Rather, most negotiations are (or at least have the potential to become) collaborative problem-solving exercises in which the parties work together to devise creative, 'win–win' outcomes. Given this view of negotiation, the problem-solving model counsels negotiators to focus on the parties' underlying interests in negotiation, to devise creative options that help satisfy both parties' interests, and to develop and use legitimate, objective criteria that both parties view as applicable to the negotiation (Fisher and Ury, 1991). The problem-solving model, in short, emphasizes both creating and claiming value in negotiation.

Neither of the primary negotiation models is sufficient to capture the complexity of legal negotiations as an empirical matter, and in all likelihood neither is sufficient as a prescriptive guide, either. Lawyer-negotiators no doubt do, and probably should, borrow liberally from either or both negotiation model(s) depending upon the nature of the negotiation, relationship between the clients, practice area, norms in the community, and relevant legal standards and rules (see also Korobkin, 2008).

Available empirical evidence suggests, however, that lawyer-negotiators tend to rely somewhat more heavily on one model or the other when negotiating. According to one empirical study, for instance, lawyer-negotiators evaluating their adversaries rated 65% of them as cooperative or problem-solving negotiators, 24% as competitive or adversarial negotiators, and only 11% as incapable of categorization (Williams, 1983). A more recent study obtained similar results, with 64% of lawyer-negotiators classified as problem-solving negotiators and 36% classified as adversarial (Schneider, 2002). An empirical study of American civil litigators found that most express a preference for the problem-solving model of negotiation but tend to behave more consistently with a more distributive or adversarial model of negotiation (Heumann and Hyman, 1997).

Negotiation in the Legal System

Lawyers perform many roles in America and around the world. Broadly speaking, though, lawyers' work typically falls into one of two categories: deal-making and dispute resolution. Negotiation is central to both.

Deal-Making

Many lawyers function as deal-makers. Corporate lawyers, mergers and acquisitions specialists, and securities lawyers,

among others, are deal-makers. Deal-making lawyers are 'transaction cost engineers' who use differences between the parties (e.g., one party wants to buy a good, while one wants to sell), noncompetitive similarities (e.g., licensee and licensor, both of whom want a technology to succeed), economies of scale (e.g., pooling production or consumption facilities to lower costs of a good), and the like to create value for their clients (Gilson, 1984; Gilson and Mnookin, 1995). Deal-making lawyers also strive to claim value for their clients by negotiating advantageous divisions of the value they have helped to create.

Dispute Resolution

Other lawyers function as dispute-resolvers. Civil litigators and criminal defense attorneys, for instance, are dispute-resolvers. Dispute-resolvers spend much of their professional lives helping their clients settle disputes through negotiation.

Most disputes do not require lawyers, however, because most disputants either choose to 'lump it' or to settle their disputes on their own through negotiation (Miller and Sarat, 1980–81). Once disputants have invoked the formal legal system by hiring a lawyer and filing suit, their negotiation is no longer shaped merely by informal norms but also by the law and legal system. The disputants and their lawyers negotiate, in other words, 'in the shadow of the law,' because the consequence of failing to reach a negotiated agreement is possible imposition of a binding decision by a third party, that is, a trial (Mnookin and Kornhauser, 1979).

Trials, however, are quite rare in the American civil justice system (and their occurrence is declining, Galanter, 2004), because most disputants settle their cases through negotiation. The conventional explanation of this phenomenon is economic. According to the economic model of suit and settlement, disputants and their lawyers seek to maximize value in litigation. To do so, they calculate the expected value of trial (i.e., the anticipated judgment times, and the probability it will occur, less trial costs), compare it to any settlement offer on the table, and select whichever promises to give them more value. Because the costs of trial are so much greater than the costs of settlement, most disputants opt to settle their cases through negotiation because settlement generally promises more value than trial. Trial, according to this economic account of litigation, results only when the disputants and their lawyers develop widely divergent predictions about the likely outcome at trial (Priest and Klein, 1984). As described below, however, settlements may break down for other reasons as well.

Barriers to Negotiation

Whether functioning as deal-makers or dispute-resolvers, lawyer-negotiators are likely to find that predictable barriers or impediments arise during the negotiation process to prevent them from obtaining optimal negotiation outcomes for their clients. These barriers or impediments fall roughly into three categories: strategic, psychological, and structural (Arrow et al., 1995; Mnookin, 1993).

Strategic Barriers

Strategic barriers arise where lawyer-negotiators adopt strategies and tactics, like hard-bargaining techniques, that backfire. Strategic barriers are likely to arise because lawyer-negotiators and their clients find themselves trapped in the so-called negotiator's dilemma (Lax and Sebenius, 1986). The negotiator's dilemma, like the prisoner's dilemma upon which it is based, focuses on the tension between distributive or value-claiming moves on the one hand and problem-solving or value-creating moves on the other.

Every negotiation involves something of value, which the parties can simply divide in some way (i.e., value claiming) or which they can attempt to expand and divide (i.e., value creating and claiming). Negotiators who make value-claiming moves may succeed in obtaining relatively more of the existing value, but their competitive moves are likely to inhibit the problem-solving needed to create additional value for the parties. The negotiator's dilemma refers to negotiator's tendency to focus narrowly on claiming value at the expense of creating additional value for the parties to divide.

The negotiator's dilemma is inherent in negotiation, but it is particularly likely to confound lawyer-negotiators and their clients under certain conditions. For example, because value creation depends upon common information, the negotiator's dilemma is more likely to impede successful negotiation when the parties face informational asymmetries (Gilson and Mnookin, 1995). When information is asymmetric, parties must agree to share their private information to create value, but parties may be reluctant to do so for fear that their adversaries will exploit the information they have divulged. This is particularly likely to be a problem in litigation.

Psychological Barriers

Psychological barriers arise due to predictable cognitive and motivational biases that influence the way lawyer-negotiators and their clients make predictions, interpret information, assess their adversaries, and weigh their options. Of the many psychological barriers that may arise, some of the most significant are self-serving and confirmation biases, overconfidence, reactive devaluation, the fixed-pie bias, loss aversion, and anchoring.

Lawyer-negotiators and their clients are likely to fall prey to self-serving and confirmation biases when making judgments about ensuing negotiations because people generally have difficulty interpreting information in a neutral fashion. To illustrate, researchers asked experimental participants to assess damages in a tort case arising from an automobile-motorcycle collision in which the plaintiff had sued the defendant for $100 000. The researchers assigned some participants to play the role of plaintiff and others the role of defendant, but they provided both sets of participants with identical information about the case. Despite reviewing identical information, participants interpreted it in self-serving ways. Participants evaluating the case from the perspective of the plaintiff predicted that the judge would award $14 527 more than the defendant-participants predicted, and identified a fair settlement value for the case that was $17 709 higher than the value selected by defendant-participants (Loewenstein et al., 1993).

These self-serving assessments are 'an important determinant of bargaining impasse' (Babcock and Loewenstein, 1997).

In addition to self-serving bias, lawyer-negotiators and their clients are also susceptible to overconfidence. In a recent study, attorneys were asked to describe a case they were handling, to describe their minimum goals for the representation, and to indicate how confident they were that they would meet or exceed those goals. When compared with the outcome of the cases once they were resolved, attorneys were overconfident in their estimates. They did not, however, seem to realize it – more attorneys reported meeting their original goals than actually met them (Goodman-Delahunty et al., 2010).

Not only are lawyer-negotiators and their clients likely to interpret their own positions in self-serving and overconfident ways, they are also likely to discount or devalue their adversaries' positions due to a phenomenon psychologists have labeled 'reactive devaluation' (Ross and Stillinger, 1991). Proposals offered by an opponent often seem less attractive to a negotiator than if the same proposal had been offered by another source (Ross and Stillinger, 1991; Korobkin and Guthrie, 1994b). Parties may, therefore, decline proposals that might otherwise be agreeable.

Reactive devaluation may stem, in part, from the fixed-pie bias – the assumption that the interests of the two sides are inevitably incompatible. Parties who believe the pie is fixed are likely to emphasize value claiming over value creation, and are therefore likely to miss opportunities to expand the pie (Thompson and Hrebec, 1996).

Lawyer-negotiators and their clients can also be influenced by 'anchors' – numbers that are available in the negotiator's mind, that provide a convenient starting place for judgment, and that influence outcomes, but that may not be relevant to the decision at hand (Tversky and Kahneman, 1982). Legal negotiators have been shown to be influenced by media reports of case outcomes, information about settlements in other cases, initial offers or demands, damage caps, and their own articulated aspirations (Babcock and Pogarsky, 1999; Depoorter, 2010; Korobkin, 2002; Korobkin and Guthrie, 1994; Robbennolt and Studebaker, 2003).

Finally, loss aversion is a significant psychological barrier that can arise during the negotiation process. Psychologists have found that negotiators do not experience equivalent gains and losses the same way. Rather, losses loom larger, 'generally twice as large' as corresponding gains (Kahneman et al., 1991; Kahneman and Tversky, 1984). Loss aversion may manifest itself in negotiation in a couple of different ways.

First, loss aversion is likely to affect negotiators' valuations of goods in transactional negotiations. Sellers are likely to place a higher value on goods than buyers because sellers experience the transfer of the good as a loss while buyers experience the transfer of the good as a gain. In an often-replicated study, researchers divided experimental subjects into a sellers group and a buyers group. The researchers gave members of the sellers group a coffee mug and the members of the buyers group $6.00 in cash. The researchers asked the sellers to indicate the minimum amount they would accept to sell the coffee mug, asked the buyers to indicate the maximum amount they would pay for a mug, and informed all of the subjects that they would execute trades based on the responses given. The researchers found that the two groups valued the mugs quite differently. Sellers, who would experience a loss if they parted with their mug, assigned a median price of $5.25, while buyers, who would experience the attainment of the mug as a gain, assigned a median price of $2.25 to $2.75 (Kahneman et al., 1991). In short, sellers tend to value goods much more highly than buyers, which may prevent lawyer-negotiators from obtaining optimal outcomes for their clients in transactional negotiations.

Second, loss aversion may influence the way negotiators perceive concessions. Negotiators view concessions they make as losses but concessions they receive from the other side as gains. Because losses are weighted more heavily than gains, negotiators are likely to view the concessions they make as more significant than the equivalent concessions their adversaries make. This 'concession aversion' may also undermine successful negotiation (Kahneman and Tversky, 1995).

Each of these psychological barriers can create a serious problem, particularly when the parties distrust one another, as is often the case in negotiation. Indeed, simply being in an adversary posture can distort negotiation judgments. For example, people tend to attribute disagreement to bias on the part of their counterpart – rather than to simple disagreement. Such attributions can incline parties to negotiate more competitively (Kennedy and Pronin, 2008).

Structural Barriers

The third type of barrier that may arise in negotiation is structural. Structural barriers are a product not of individual negotiators' calculations or cognitive processes but rather of the way in which conflict and conflict resolution are managed. The most significant structural impediment to successful negotiation faced by lawyer-negotiators and their clients arises out of the lawyer–client relationship.

The lawyer–client relationship is a classic principal–agent relationship (Pratt and Zeckhauser, 1985), in which the client is the principal who possesses substantive decision-making authority, while the lawyer is an agent who is ethically obligated to use legal means to carry out the client's objectives. The structure of this relationship can facilitate settlement as well as pose barriers to agreement. Lawyers, as third parties to a dispute or deal, can sometimes help clients avoid psychological barriers to agreement (Gilson and Mnookin, 1994; Korobkin and Guthrie, 1997). But, as with any principal–agent relationship, incentives are seldom perfectly aligned between principal and agent. This misalignment of incentives can have a detrimental impact on negotiation.

To give one concrete illustration, consider a typical personal injury lawsuit in the United States. In such a case, the plaintiff is usually a one-shot player with limited resources who hires a lawyer on a contingency fee basis, while the defendant is often a repeat-player organization of some type that hires a lawyer on an hourly fee basis (Galanter, 1974; Gross and Syverud, 1996; Kritzer, 2002). Principal–agent problems may arise for both plaintiffs and defendants.

The plaintiff's lawyer who takes the case on a contingency basis recovers a fee only if the plaintiff succeeds in obtaining a settlement or judgment. If the plaintiff is successful, the plaintiff's lawyer will receive a percentage of the recovery. Because of this financing scheme, the plaintiff's lawyer may have an incentive to settle quickly so as to maximize his hourly

return, but the plaintiff may fare better if the plaintiff's lawyer settles later or takes the case to trial. Suppose, for instance, that a plaintiff's lawyer on a 25% contingency settles a case for $10 000 after 10 h of work. In this instance, the plaintiff receives a net recovery of $7500, and the plaintiff's attorney receives $2500 for his efforts. On an hourly basis, the plaintiff's attorney earns a $250 per hour wage. Now suppose instead that the plaintiff's lawyer settles the case for $16 000 after conducting 40 h of work. In this instance, the plaintiff does better, obtaining a net recovery of $12 000. By contrast, the plaintiff's attorney does worse, earning only $100 per hour for his efforts (i.e., $4000 for 40 h of work). In short, the plaintiff's attorney would do better to settle earlier, while the plaintiff would do better to settle later.

Defense counsel working on an hourly fee basis faces a very different incentive structure than the plaintiff's lawyer. Defense counsel's hourly wage is constant regardless of the number of hours worked. Thus, defense counsel has a financial incentive to work the case as long as possible because that will maximize earnings. The client, in contrast, is likely to fare better if the case settles earlier. Suppose, for instance, that defense counsel charging $200 per hour settles a case for $10 000 after working 10 h on the case. In this instance, settlement costs the defendant $12 000 (i.e., $10 000 to plaintiff and $2000 to defense counsel) and earns defense counsel $2000. Now suppose, instead, that defense counsel settles for $6000 after spending 40 h on the case. In this instance, settlement costs the defendant more (i.e., $6000 to plaintiff and $8000 to defense counsel) but earns defense counsel more (i.e., $8000 vs $2000). In short, the defense counsel would do better to settle later, while the defendant would do better settling earlier.

Other considerations also play a role in how attorneys advise clients about when and how to settle cases – considerations including concern for reputation and referrals, the demands and promise of other cases, and many more (Kritzer, 2002). Legal negotiators must constantly weigh all of these competing considerations (see Robbennolt et al., 2010).

The Future of Negotiation Research

Because of its importance in law, business, foreign affairs, and interpersonal relationships, negotiation will continue to attract the attention of scholars and practitioners trying to shed light on the process. Three research trends are likely. First, scholars will propose additional models of negotiation that combine or challenge the existing distributive and problem-solving models of negotiation. Second, scholars will explore opportunities that new communications technologies create (as well as problems they cause) for negotiation (see, for example, Thompson and Nadler, 2002). Finally, scholars will continue to conduct empirical and experimental investigations into barriers to optimal negotiation outcomes. Ideally, scholars will not only identify additional barriers but will develop some appreciation of the magnitude of these barriers, learn more about how the barriers might interact with one another, and devise prescriptions for overcoming the barriers. Continued investigation of the negotiation process is important because negotiation will continue to be the process by which most disputes are resolved and most deals get done.

Abstract

Although conflict is associated with higher levels of emotion than negotiation, the two processes share many similarities. Both disputants and negotiators can opt for a more cooperative or competitive approach to resolving their differences. The approach that they choose and its consequences are affected by the social context within which conflicts and negotiations take place, the social processes that emerge as conflicts and negotiations unfold, and individuals' thoughts and feelings. This article explores how variables such as power, gender, culture, communication, and emotion influence the reconciliation of conflicting interests.

Negotiation and conflict are linked by the strategic options available to individuals. In both domains, two-dimensional typologies set out options based on the relative importance that individuals place on protecting their interests and outcomes *or* preserving their relationships with the other party. Typologies such as Pruitt's Dual Concern Model (Pruitt, 1981) and Rahim's Conflict Styles (Rahim, 1983) identify four strategic options: competition (protects outcomes, damages relationship); accommodation (erodes outcomes, preserves relationship); avoiding (erodes both outcomes and relationship); and problem solving (preserves or strengthens both outcomes and relationships). Of these, problem solving offers the most constructive path forward in both negotiations and conflicts. However, finding and following this path is difficult for negotiators and disputants alike. Consequently, negotiation and conflict researchers have focused on identifying the conditions that facilitate or impede a problem-solving approach. In both domains, researchers have explored the role of the social context, cognition, and emotion in influencing the strategies that individuals favor. Increasingly, researchers are also interested in how negotiators and disputants can turn a dysfunctional competitive process into a more constructive problem-solving one, and in the conditions that support this change.

The Psychology of Negotiation

Negotiators strive to balance two conflicting goals, the goal of maximizing individual outcomes and the goal of maximizing joint outcomes. The maximization of individual outcomes requires negotiators to claim value, that is, to persuade the other party to make favorable concessions and to yield to their demands. However, if negotiators are too unrelenting in their demands, they risk triggering escalatory cycles of argumentation and deadlock. In contrast, the maximization of joint outcomes requires that negotiators create value by sharing information, revealing their own interests and uncovering those of their counterparts. While value creation offers the benefit of increasing resources, the openness that underpins value creation also exposes negotiators to the risk of exploitation by their counterparts. Nonetheless, without creating value, negotiators are unlikely to reach a mutually acceptable agreement. Recognizing the tension between these processes, negotiation researchers have focused on identifying the factors that lead negotiators to emphasize value creation over value claiming, or vice versa. Four broad themes have emerged from this research: social context, social processes, social perception, and cognition and emotion.

Social Context

The social context within which negotiations take place shapes the way that individuals approach their negotiation. Social context is defined by factors considered to be 'outside' of the negotiation, that is, factors other than the issues to be negotiated. A unifying theme in this research is the representation of the underlying negotiation relationship, which may emphasize either independence or interdependence. Negotiators are less likely to believe that their fate (and outcome) is intertwined with that of an opponent when the social context emphasizes independence than when it emphasizes interdependence. As a result, negotiators with an independent perspective are more likely to favor value claiming than those with an interdependent perspective. Conversely, negotiators with an interdependent perspective are more likely to favor value creating than those with an independent perspective (Gelfand et al., 2006). Among the variables that can push negotiators to a more independent or interdependent representation of their relationship with an opponent, four have dominated negotiation research: social motives, power, gender, and culture.

Social Motives

Social motives capture the goals that negotiators have at the outset of a negotiation. These goals can be either *individualistic* and emphasize the maximization of individual outcomes or *cooperative* and emphasize the maximization of both negotiators' outcomes. One of the most enduring findings in negotiation research is that an individualistic motive encourages competition whereas a cooperative motive encourages problem solving (De Dreu et al., 2000). Negotiators with an individualistic orientation favor strategies such as argumentation, threats, and demands and consequently claim a greater share of resources for themselves. Negotiators with a cooperative orientation favor strategies such as information exchange, relationship building, and concession exchange, consequently creating greater value than individualistic negotiators. Differences in social motives maybe the result of explicit instructions

given to negotiators or may occur 'naturally' as the result of individual differences.

Power

Power resides both with the individual negotiator and with the negotiating dyad. Individuals may start negotiations with either high or low personal power, typically defined as the number of alternative options available to negotiators (Kim et al., 2005). Negotiators who have many available alternatives also have high power because of the greater ease with which they can exit an unsatisfactory negotiation. As a result, they are less concerned than low-power negotiators about preserving their relationship with an opponent. Tactically, this lack of concern is evident in their willingness to make more extreme offers and to give fewer concessions than low-power negotiators. As a result, high-power negotiators typically claim a greater share of resources than do low-power negotiators.

Power cannot, however, be fully understood at the individual level. It is also necessary to consider how power is distributed between two negotiators because power distribution determines negotiators' level of dependence. When power is evenly distributed (both negotiators have many or few alternatives), they are mutually dependent. Under conditions of mutual dependence the advantages of high power and the disadvantages of low power are reduced: having many alternative options is an advantage only if the other party has few and having few alternative options is a disadvantage only if the other party has many. When power is asymmetrically distributed (one negotiator has many and the other has few alternatives), they are nonmutually dependent. One consequence is that contention rapidly escalates: both the high- and low-power negotiators use more threats, personal attacks, and persuasive arguments. A further consequence is that negotiators are more likely to create value when negotiators are mutually dependent than when they are nonmutually dependent.

Gender

Early research found gender differences in negotiation to be somewhat elusive. Although women and men obtained markedly different outcomes in their negotiations, meta-analyses showed that only a small proportion of the variance in outcomes could be attributed to differences in the level of competitiveness that they displayed (Walters et al., 1998). More recent research shows that women's poorer negotiations are the result of both how women approach negotiations and the responses that they elicit from their opponents. A fundamental difference is women's greater reluctance to initiate negotiations. The failure to 'ask' means that women deprive themselves of the opportunity to improve their outcomes or meet their needs. Even when they do ask, they typically negotiate in a more narrow domain than men, seeing less of the world as negotiable. Those women who do initiate negotiations underestimate their worth: they set lower targets; are more likely to accept the first offer that they receive; and are less likely to walk away from an offer that does not meet their needs. These actions on the part of women are complemented by those of their opponents, who make lower offers to women based on the assumption that these offers will be accepted. Each of these actions erodes women's economic outcomes. Recent research shows that women obtain better outcomes when they believe that problem solving is linked to effective negotiation, and when there is transparency about what is negotiable.

The negotiation landscape is further complicated because women need to be mindful of both their economic and social outcomes. While women who initiate negotiations can improve their economic outcomes, this improvement carries a social cost. Irrespective of how they approach a negotiation, the initiation of a negotiation in its own right results in women being perceived as more pushy, less likable, and less desirable work colleagues. Women can offset these social costs by negotiating on behalf of others, by attributing the initiation of a negotiation to a mentor, or by harnessing female gender stereotypes (Kray and Thompson, 2005; Kulik and Olekalns, 2012).

Culture

Two dimensions dominate research linking cultural differences to negotiation tactics and outcomes, communication style, and individualism–collectivism (Brett, 2007). The first of these dimensions reflects cultural preferences for direct (low-context) vs indirect (high-context) communication; the second of these dimensions differentiates cultures based on the emphasis placed on individuals or groups. Drawing on these dimensions, researchers have shown that low-context negotiators favor giving and seeking explicit information about their underlying priorities and preferences, and that high-context negotiators are more likely to learn about each others' priorities and preferences indirectly through the exchange of multiple offers. These strategies work equally well to create value in intracultural negotiations but these different communication preferences impede value creation in intercultural dyads.

The structure of communication is shaped by communication styles. Negotiators are more likely to reciprocate emotional appeals in the opening moments of a negotiation when they are both from a low-context culture, than when they are from a high-context culture or when they have different communication styles. They are more likely to reciprocate offers over time when both negotiators have the same communication style than when they do not. And, when at least one negotiator is from a low-context culture, negotiators are progressively less likely to respond to emotional appeals with direct information about priorities as the negotiation progresses.

In a comparison of Asian cultures, researchers showed that Chinese negotiators are less likely than Japanese or Korean negotiators to use rational influence or share information about underlying priorities, and that Korean negotiators are less likely than Japanese or Chinese negotiators to make emotional appeals in order to improve their outcomes. These findings demonstrate that we need to focus not just on a single cultural dimension, but on a cluster of cultural dimensions, in order to understand how culture shapes negotiations.

Social Processes

Not all of the variance in negotiators' outcomes can be attributed to the social context within which negotiations occur: negotiators in the same objective conditions do not obtain identical outcomes. For example, not all negotiators with an individualistic social motive fail to create value and not all

negotiators with a cooperative social motive succeed in creating value. This observation has led negotiation and communication scholars to focus on the 'black box' of negotiation, that is, to try and link what negotiators say and do as a negotiation unfolds to their outcomes.

Strategies and Tactics

To unpack the black box, researchers have focused on the tactics that negotiators use and when they use them. Tactics can be classified according to the information that they provide (positional vs priority), the kind of relationship that they signal (dominance vs affiliation), the management of offers and concessions, and the management of the negotiation process. To understand the relationship between these tactics and negotiation outcomes, negotiation researchers have focused on the frequency with which they are used, how they are sequenced, and when in a negotiation they occur (Adair and Loewenstein, 2013).

The frequency with which strategies are used provides important information about a negotiator's dominant strategic orientation. As strategies accumulate over time, they convey either a dominant cooperative or a dominant competitive orientation. Negotiators who give and ask for information about underlying needs and priorities, who emphasize affinity and an equal relationship, and who are willing to intervene and redirect a negotiation away from competitive tactics signal their intention to cooperate. Conversely, negotiators who favor a pattern of argument and counterargument, who assert power and dominance, and who consistently make demands and threats signal their intention to compete. Unsurprisingly, whereas a broadly cooperative strategy supports value creation, a broadly competitive strategy supports value claiming.

Focusing on how strategies are sequenced, that is what one negotiator says and how his/her opponent responds, provides insight into the moment-to-moment tactical decisions that negotiators make as they strive to move toward their goals. Strategy sequences fall into one of three broad categories: reciprocal, complementary, or transformational. Both reciprocal sequences, in which negotiators exactly match each others' tactics (e.g., a demand from one negotiator elicits a demand from the other), and complementary sequences, in which negotiators match each others' overall strategic orientation (e.g., a demand from one negotiator elicits a threat from the other) preserve the overall strategic tone of a negotiation. They hold negotiators in a broadly competitive or cooperative dynamic. Transformational sequences, in which negotiators mismatch tactics (e.g., a demand from on negotiator elicits a question about underlying needs and interests from the other), offer negotiators the opportunity to change the dominant strategic tone of their negotiation. The analysis of strategy sequences demonstrates that negotiators who create competitive cycles by continually reciprocating each others' competitive tactics at best obtain very poor outcomes and at worst fail to reach agreement. Conversely, negotiators who reciprocate each others' cooperative strategies are better able to create value. Finally, this research shows a complex link between social context, strategy sequences, and paths to value creation. It shows that the strategies and strategy sequences that facilitate successful value creation vary as function of negotiators' social motives, their power, and their culture.

Phases and Interruptions

As negotiations unfold over time, there are shifts in the dominant tactics and strategies that negotiators use. Stage models of negotiation represent these shifts as occurring in an orderly way, and as necessary to move negotiations from beginning to end. These models describe a process in which negotiators start by positioning in order to identify the constraints on the negotiation, move to information exchange in order to create value, and then shift back to a more competitive approach to claim value. Phase models represent the process as a more fluid one in which strategy switches occur more frequently as negotiators strive to navigate specific obstacle to agreement (Brett et al., 2004).

Although both stage and phase models capture the emergent aspect of negotiations, they do not address the question of what triggers stage or phase shifts. The answer to this question lies in turning points (Druckman and Olekalns, 2013), events that introduce an element of surprise into negotiations because they violate negotiators' expectations. A key feature of turning points is that they are highly salient events that stand out from the flow of an ongoing negotiation, inviting greater scrutiny of an opponent's actions, and triggering a search for explanations. As a result, they can alter the underlying relationship or the entire negotiation process. For example, when turning points lead to negative attributions about an opponent's intentions they erode trust whereas when they lead to positive attributions about an opponent's intentions they build trust. Turning points may be triggered by internal processes, often occurring when one negotiator violates the expectations of an opponent. However they may also be triggered by external events such as policy and leadership changes, third-party interventions, or the introduction of new information. In either case, they provide an opportunity to change the overall flow of the negotiation either by changing the process to facilitate or inhibit agreement.

Social Perception

The opening moments of a negotiation are characterized by uncertainty and ambiguity. While negotiators are fully cognizant of their own goals and intentions, at best they have only partial information about the goals and intentions of their opponents. Because negotiators' strategy choices are, in part, determined by their assessment of whether the other party will treat them fairly or attempt to exploit them, this uncertainty needs to be resolved early in the negotiation. Consequently, negotiators rely on thin-slicing, the use of limited information and intuition, to form an impression of others' intentions. This process is critical to how negotiations unfold, with the opening moments of a negotiation predicting final outcomes (Curhan and Pentland, 2007).

Trust and Trustworthiness

The first judgment that negotiators make is about their opponents' trustworthiness. Determining an opponent's trustworthiness is a key task for negotiators: a trustworthy opponent invites problem solving and information exchange, whereas an untrustworthy opponent invites contention and argumentation. Like other impressions, the assessment of trustworthiness is made rapidly at the start of a negotiation and creates a frame for interpreting others' actions. It also sets

in motion a self-perpetuating cycle of trust or mistrust. Because negotiators who believe their opponent is trustworthy implement cooperative strategies, they invite cooperation from opponents establishing a virtuous cycle in which cooperation begets cooperation and builds trust. Conversely, negotiators who believe their opponents are untrustworthy implement competitive strategies, inviting competition from their opponents, and establishing a vicious cycle in which competition begets competition and erodes trust. The social context contributes to negotiators' initial assessments of trustworthiness: competitive negotiators trust others less than cooperative negotiators, and high-power negotiators are perceived as less trustworthy than low-power negotiators.

Microethical Judgments

A second judgment made by negotiators centers on exploitation. Negotiators ask not only whether they are likely to be exploited by an opponent, but may also assess the costs of acting exploitatively. The question of exploitation and exploitability leads us to the issue of how negotiators make ethical judgments, and the conditions under which they might choose to act unethically. Two models, moral pragmatism and opportunistic betrayal, provide insight into the factors that shape negotiators' ethical judgments. Moral pragmatism licenses negotiators to deceive their opponents under specific conditions. The central tenet of this model is that of self-protection. Negotiators are advised to be open and honest if they believe that their opponents will negotiate in good faith. However, if they believe that their opponents will try to exploit them, they are encouraged to withhold or misrepresent information in order to protect their interests. Moral pragmatism thus encourages a less ethical course of action when negotiators face adverse conditions. Opportunistic betrayal provides a counterpoint to this position. According to an opportunistic betrayal model, individuals including negotiators assess the relative costs and benefits of pursuing a less ethical course of action. Negotiators choose a less ethical path when benefits outweigh costs, implying that they may act less ethically when they believe the other party is well intentioned and will negotiate in good faith. Both models have been supported by research, which also shows that negotiators' decisions to withhold or misrepresent information are influenced by social context: social motives, power, regulatory focus, and gender all interact with trustworthiness to influence when and how negotiators deceive their opponents.

Cognition and Emotion

At the heart of a negotiation we find the individual. Although individuals' actions are shaped by the social context within which negotiations take place, what opponents say and do and the intentions that they convey are also shaped by individuals' thoughts and feelings. How negotiators represent their task, how they process information, and how they use and respond to emotion displays, all influence their strategy choices and outcomes.

Negotiators' Cognition

One of the earliest directions in negotiation research was the integration of negotiation theory with behavioral decision-making theory (Neale and Bazerman, 1991). Drawing on Prospect Theory, this research showed that negotiators' are influenced by their decision frames. Negotiators who represent their outcomes as losses are more risk seeking, make higher opening offers, and give fewer concessions than negotiators who represent their outcomes as gains. Continuing to draw on behavioral decision theory, researchers have also demonstrated that negotiators are overconfident and that they will obtain a better outcome than their opponents. When they open negotiations, they are able to anchor their opponents' expectations and so shift the negotiation in their favor. Like other decision makers, negotiators also show an egocentric bias in relation to their own costs and reactive devaluation of opponents' costs (Thompson and Hastie, 1990). The focus on decision biases and heuristics also identified two negotiation-specific biases: the fixed-pie bias, capturing the assumption that negotiators' interests are necessarily opposed, and the incompatibility bias, capturing negotiators' failure to recognize points of commonality.

Drawing on social cognition, researchers have also shown negotiators to be motivated information processors (De Dreu and Carnevale, 2003). Given the central role of accurate information in the value-creation process, negotiators' motivation to undertake an exhaustive search for information is of particular interest. The willingness to search for information is determined by individuals' epistemic motivation. Individuals with high epistemic motivation report less certainty and confidence than individuals with low epistemic motivation. As a result, they are more likely to engage in extensive information than to rely in heuristics to guide their decision making. Negotiators with high epistemic motivation spend more time searching for information about their opponents' underlying priorities and preferences and are consequently better able to create value. Epistemic motivation is sensitive to the negotiation context, and is higher when individuals have competitive goals, when they represent outcomes in terms of losses, and when they have low power. Koning and Van Dijk (2013) conclude that epistemic motivation decreases as negotiators' cognitive load increases.

Negotiators' Emotion

Although negotiators' cognitions and emotions work in parallel to shape negotiations, the focus on emotions in negotiation is relatively recent (Barry et al., 2004). The first stream of research focused on negotiators' felt emotion and investigated the impact of positive or negative emotions on information processing. This research showed that positive emotions such as happiness and optimism increase negotiators' concerns about their relationship with opponents, and as a result they favored cooperation and concessionary behavior over competition. This effect on negotiators' strategy choice was underpinned by the different expectations that positive and negative emotions induce. Whereas negotiators who report negative emotions also report low trust and the expectation that negotiations will be difficult, those who report positive emotions also report high trust and expect to reach agreement with their opponents. Recent research also links felt emotions to ethical judgments: negotiators who experience positive effect are less likely to deceive their opponents than those who experience negative effect.

Expressed emotions shape the reactions that negotiators elicit from their opponents. Researchers have predominantly focused on anger and consistently show that expressions of anger elicit concessions from opponents. The greater willingness to give concessions in the face of anger is triggered by the inference that anger signals high limits and because anger induces fear in negotiators. A smaller body of research explores other negative emotions: negotiators who experience guilt or regret are more likely to cooperate, whereas negotiators who feel disappointed are less likely to cooperate. Expressed positive emotions, on the other hand, increase the likelihood both that an agreement will be reached and that it will be implemented, and preserve future relationships. In high stakes negotiations such as hostage negotiations, the reciprocation of positive emotions by negotiators and hostage-takers facilitates a successful conclusion.

The Psychology of Conflict

Conflicts arise because one or more people (or groups) believe that they have incompatible goals. There are several factors that might lead to these incompatibilities: individuals believe others are blocking their plans and goals, scarce resources need to be divided, individuals rely on others to complete tasks, or they disagree about the best path to achieving their goals. Two factors differentiate conflicts from negotiation. The first factor is that, by the time conflicts surface, communication between individuals or groups has broken down. This means that individuals need to reestablish communication and trust before they can resolve the substantive conflict. The second factor is the higher negative emotion that typically accompanies conflicts, making it more difficult to reestablish communication.

Research in both field and experimental settings has focused on identifying the factors that trigger and escalate conflict. Many of the themes that characterize negotiation are also evident in conflict research: social context, cognition, and emotion all shape how individuals characterize and react to conflicts. Unlike negotiation researchers, conflict researchers have also focused identifying and understanding different kinds of conflicts.

Typology of Conflicts

Conflict can occur because individuals have different ideas and opinions about a task (task conflict), about the responsibilities assigned to different team members in order to accomplish the task (process conflict), or may be unrelated to the task and instead highlight differences in personal values or individuals' styles (relationship conflict). For some time researchers believed that task conflicts could be beneficial because they stimulated performance, whereas relationship conflicts would always block progress toward task completion. Although an early meta-analysis showed that team satisfaction and performance decrease as *either* task or relationship conflict increased (De Dreu and Weingart, 2003), more recent meta-analyses of the role that task, relationship, and process conflict play in achieving group goals show the relationship between conflict type and outcomes is more complex. All three types of conflict reduce trust and group member commitment. Task and relationship conflict reduce organizational citizenship behavior and counterproductive workplace behavior. In the case of relationship conflict, this effect is moderated by relational closeness. Relationship and process conflict reduce group member satisfaction and group performance, and relationship conflict reduces group member cohesion and positive affect. Turning to antecedents of conflict, stretch goals are found to intensify relationship conflicts unless there is a strong interpersonal justice climate.

Two meta-analyses suggest that the negative relationship between task conflict and performance is moderated by task type: decision-making teams and top-level management teams appear to benefit from task conflict (De Wit et al., 2012; O'Neill et al., 2013). Recent research also shows that psychological safety climate and the importance of the issues under dispute may be important moderators of the task conflict–performance relationship. Moreover, the co-occurrence of task and relationship conflicts moderates the relationship between task conflict and group performance. Finally, in analyzing how different types of conflict emerge over time, researchers have shown that task conflict leads to relationship conflict because it generates negative affect whereas relationship conflict leads to task conflict because it reduces trust in group members.

Social Context

The social contextual variables that influence negotiations also influence conflicts. In particular, research has focused on how gender and culture influence individuals' preferences for different conflict resolution styles. The underlying assumption in both streams of research that an interdependent relational orientation will lead disputants to favor relationship-preserving strategies such as avoidance and accommodation, whereas an independent relational orientation will lead disputants to favor self-oriented strategies such as competition (Gelfand et al., 2006).

Gender

Paralleling the relationship between gender and negotiation styles, gender also affect the conflict styles that individuals use and how those styles are perceived by others (Olekalns, 2014). There is consistent evidence that women favor constructive approaches to conflict resolution such as problem solving and compromise whereas men favor a more relationally damaging competitive approach. Organization-based research shows that, in response to a conflict, men express more anger than women. These gender-congruent approaches carry over from direct conflicts to situations that include a mediator. In divorce mediations, women continue to favor conciliatory strategies, focusing on their contributions to the relationship and the sacrifices that they have made whereas men focus on legal and rational arguments to justify their claims. As mediators, women favor process-oriented interventions but men favor directive action. How others respond to conflict styles is also influenced by gender. For example, mediators' trustworthiness is affected by gender: impartiality predicts trust in female mediators but empathy predicts trust in male mediators.

Culture

Research exploring cultural differences in conflict resolution typically compares individualistic and collectivist cultures.

An underlying assumption is that individualistic cultures are less concerned about preserving social harmony and face than collectivist cultures, and this difference leads them to favor different conflict resolution strategies, specifically leads individuals from collectivist cultures to favor avoidance. In reality, the relationship between culture and conflict resolution is more nuanced. First, the cultural groups frame conflicts differently. For example, whereas Japanese frame conflicts in terms of compromise and obligation, Americans frame them in terms of winning and infringements of self. Second, they respond to conflicts differently. Recent research shows that conflicts that incur loss of face are more likely to lead to anger and relational damage in collectivist than in individualistic cultures. In managing workplace conflicts, collectivists (Chinese) report they are more likely to embarrass their colleagues and to try and teach them a moral lesson, whereas individualists are more likely to report hostility and a desire for revenge. The two cultural types also report different preferences for third-party interventions: whereas collectivists favor interventions that help them to treat each other respectfully, individualists (Dutch) favor interventions that provide emotional comfort and convey a willingness to listen. Third, the consequences of conflict also differ: individualists report psychological strain in response to direct conflict whereas collectivists (Chinese) report physical symptoms of stress in response to indirect conflicts.

Cognition and Emotion

Unlike analyses of negotiators' cognition, which focus on individual information processing, analyses of disputants' cognition focus on the broad perspective through which disputants filter information. These conflict frames shape both how disputants approach a conflict and their expectations about an acceptable resolution. Finding this solution is more challenging because of the negative emotions that imbue disputes and block communication.

Disputants' Cognition

The cognitive processes that shape our understanding of conflicts have been analyzed at two distinct levels. The first level focuses on the broad perspective that individuals bring to their conflicts, that is, their conflict frames. Individuals may view their conflicts from one of three frames: power, which tests whether one disputant has greater power than the other to impose a settlement; rights, in which disputants focus on contractual obligations as a mechanism for resolving conflicts; or interests, in which disputants use a problem-solving strategy to identify a mutually acceptable solution. Both power and rights frames result in a more competitive and escalatory process than does an interest frame, especially when disputants reciprocate each other's frame. A central question is how disputants can break out of reciprocal power-rights spirals and redirect the dispute to an interest-based frame (Brett et al., 1998).

More recent research explores how individuals' process information based on their group membership. This research shows that information processing is affected by whether or not individuals who represent their groups in a conflict resolution process perceive themselves to be central to their group. Group centrality is thought to affect individuals' sense of security, and as a result affect their epistemic motivation. Recent research reports that peripheral members report higher levels of epistemic motivation, recall more information, and are more likely to identify mutually beneficial solutions, but only when they are accountable to group members (Van Kleef et al., 2013).

Disputants' Emotion

Anger functions differently in disputes: whereas expressed anger elicits concessions in negotiation, in disputes expressed anger elicits retaliation and reciprocal expressions of anger because disputants perceive it to be unfair. Unsurprisingly, expressions of anger work against agreement delaying or even stalling settlement. The negative consequences of anger can be offset if the anger elicits a sincere apology or softens the tone of communication. Venting, on the other hand, can increase anger if it is directed at third parties rather than individuals directly involved in a conflict. Other emotions affect the strategies that disputants choose to resolve conflicts. Cooperative strategies such as integrating, compromising, and yielding are facilitated by positive emotions in intragroup conflicts and by guilt in divorce mediations. Competitive strategies such as forcing and dominating are elicited by negative emotions in intragroup conflicts and by shame in divorce mediations. Finally, at least in child custody disputants, when husbands mirror their wives positive emotions, settlement becomes more likely.

Anger also influences how intergroup conflicts unfold. Contrary to the more usual perception that expressing anger is dysfunctional, recent research shows that it may reduce intergroup conflict if it is interpreted as signaling the value of the long-term relationship between the groups thereby evoking empathy. This effect may depend on timing. If expressed when a conflict is escalating, anger triggers negative consequences; if expressed after sustained attempts to de-escalate conflict it results in positive consequences. Finally, in intergroup conflicts, felt emotions are shaped by context. In intergroup conflicts, out-group members who are perceived as less warm elicit anger, whereas those who are perceived as less competent elicit contempt. These effects are underpinned by the attribution of negative intentions in the case of low warmth, and increased concerns about lack of control in the case of low competence.

Negotiations: Statistical Aspects

James K Sebenius, Harvard Business School, Harvard University, Boston, MA, USA

Abstract

'Negotiation analysis' seeks to develop prescriptive theory and useful advice for negotiators and third parties. It generally emphasizes the parties' underlying interests, alternatives to negotiated agreement, approaches to productively manage the inherent tension between competitive actions to 'claim' value individually and cooperative ones to 'create' value jointly, as well as efforts to change perceptions of the game itself. Since advice to one side does not necessarily presume the full game-theoretic rationality of the other side(s), negotiation analysts often draw on the findings of behavioral scientists and experimental economists. Further, this approach does not generally assume that all the elements of the 'game' are common knowledge. It tends to de-emphasize the application of game-theoretic solution concepts or efforts to find unique equilibrium outcomes. Instead, to evaluate possible strategies and tactics, negotiation analysts generally focus on changes in perceptions of the 'zone of possible agreement' and the (subjective) distribution of possible negotiated outcomes conditional on various actions. It has been used to develop prescriptive advice for the simplest bilateral negotiations between monolithic parties, for negotiations through agents, or with linked 'internal' and 'external' aspects, for negotiations in hierarchies and networks, as well as for more complex coalitional interactions.

Introduction

The term 'negotiation analysis' encompasses an emergent body of work that seeks to generate prescriptive theory and advice for parties wishing to negotiate in a 'rational' manner, without necessarily assuming that the other side(s) is a strategically sophisticated, rational actor.

To what bodies of theory and empirical work might one turn for advice in a negotiation over selling a car or forging a global warming treaty? Decades of psychological studies of people negotiating offer many powerful insights but generally lack a prescriptive theory of action. Instead, this behavioral approach has largely sought accurate descriptions and analytic explanations of how negotiators do act. What they should do often remains an implicit or ad hoc implication of this careful work.

Decision analysis, the practically oriented cousin of decision theory, would seem a logical candidate to fill this prescriptive void. It suggests a systematic decomposition of the problem: structuring and sequencing the parties' choices and chance events, then separating and subjectively assessing probabilities, values, risk, and time preferences. A von Neumann–Morgenstern expected utility criterion aggregates these elements in ranking possible actions to determine the optimal choice. This approach is well suited to decisions 'against nature,' in which the uncertainties – such as the probability that a hurricane will strike Miami in August – are not affected by the choices of other involved parties anticipating one's actions.

Yet when decision-making is interactive – as is true in negotiation, where each party's anticipated choices affect the other's and vice versa – assessment of what the other side will do qualitatively differs from assessment of 'natural' uncertainties. Of course, the theory of games was developed to provide a logically consistent framework for analyzing such interdependent decision-making. Full descriptions of the courses of action open to each involved party are encapsulated into 'strategies.' Rigorous analysis of the interaction of strategies leads to a search for 'equilibria,' or plans of action such that each party, given the choices of the other parties, has no incentive to change its plans. A great deal of analysis by game theorists seeks conditions for unique equilibria among such strategies (von Neumann and Morgenstern, 1944; Luce and Raiffa, 1957; Aumann, 1989).

Game theory has been especially useful for understanding repeated negotiations in well-structured financial situations. It has offered useful guidance for the design of auction and bidding mechanisms, has uncovered powerful competitive dynamics, has usefully analyzed many 'fairness' principles, and now flourishes both on its own and in applications such as microeconomic theory. Despite signal successes, the dominant game-theoretic quest to predict equilibrium outcomes resulting from the strategic interactions of fully rational players often lacks prescriptive power in negotiations.

Three major aspects of mainstream game theory, discussed at length in Sebenius (1992), contribute to this 'prescriptive gap.' First, on standard assumptions, there are often numerous plausible equilibrium concepts, each with many associated equilibria – and no a priori compelling way to choose among them. Second, even where one party wishes to act rationally, the other side may not behave as a strategically sophisticated, expected utility-maximizer – thus rendering conventional equilibrium analyses less applicable. A large and growing body of evidence – especially in 'behavioral game theory' and experimental economics – suggests that people systematically and significantly violate the canons of rationality. Third, the elements, structures, and 'rules' of many negotiating situations are not completely known to all the players, and even the character of what is known by one player may not be known by another. The frequent lack of such 'common knowledge' limits – from a prescriptive standpoint – much equilibrium-oriented game analysis, though recent work has begun to relax the widespread understanding that common knowledge of the situation was essential to game models (Aumann and Brandenburger, 1995). Even where it is possible to bend such a situation

into the form of a well-posed game, and gain insights from it, the result may lose prescriptive relevance.

The Negotiation Analytic Response

If descriptive psychological approaches to negotiation lack a prescriptive framework, if decision analysis is not directly suited to interactive problems, and if traditional game theory presupposes too much rationality and common knowledge, then 'negotiation analysis' represents a response that yokes the prescriptive and descriptive research traditions (Sebenius, 2009). Using Howard Raiffa's (1982) terms, unlike the 'symmetrically prescriptive' approach of game theory, wherein fully rational players are analyzed in terms of what each should optimally do given the other's optimal choices, the 'asymmetrically prescriptive/descriptive' approach typically seeks to generate prescriptive advice to one party conditional on a (probabilistic) description of how others will behave. This need not mean tactical naiveté; as appropriate, the assessments can incorporate none, a few, or many rounds of 'interactive reasoning.'

Works that embody the spirit of this work can be found as early as the late 1950s. While Luce and Raiffa's *Games and Decisions* (1957) was primarily a brilliant synthesis and exposition of game theory's development since von Neumann and Morgenstern's (1944) classic work, Luce and Raiffa began to raise serious questions about the limits of this approach in analyzing actual interactive situations. Perhaps, the first work that could be said to be in the spirit of 'negotiation analysis' was *The Strategy of Conflict* by Thomas Schelling (1960). Its point of departure was game-theoretic, but it proceeded with less formal argument and the analysis had far broader direct scope. Though nominally in the behavioral realm, Walton and McKersie's *Behavioral Theory of Labor Negotiation* (1965) drew on Schelling's work as well as rudimentary decision and game theories.

The first overall synthesis of this emerging field appeared with Raiffa's (1982) *The Art and Science of Negotiation*, elaborated in Raiffa et al. (2002). Building on Sebenius (1984), this approach was systematized into an overall method in Lax and Sebenius' *The Manager as Negotiator* (1986) and *3D Negotiation* (2006). *Negotiation Analysis* (1991), edited by Peyton Young, furthered this evolving tradition, which was characterized and analytically evaluated in Sebenius (1992). Further contributions in the same rationalist vein were included in Zeckhauser et al. (1996), Arrow et al. (1995), Subramanian (2011), and, adding insights from organizational and information economics, in Mnookin et al. (2000).

Meanwhile, another group of researchers was coming to a negotiation analytic view from a behavioral point of departure. With roots in the cognitive work of behavioral decision theorists, e.g., Bell et al. (1988), behavioral scholars began in the early 1990s to explicitly link their work to that of Raiffa and his colleagues. In particular, Neale and Bazerman's *Cognition and Rationality in Negotiation* (1991), Bazerman and Neale (1992), and Thompson (2011) pulled together and developed a great deal of psychological work on negotiation in an asymmetrically prescriptive/descriptive framework. These efforts began systematically to build up more structure on what had been, in the works of Raiffa et al. a largely ad hoc descriptive side of the ledger.

Elements of a Negotiation Analytic Approach

Full negotiation analytic accounts (e.g., Sebenius, 1992, 2000) generally consider the following basic elements: the actual and potential parties; their perceived interests; alternatives to negotiated agreement; the linked processes of 'creating' and 'claiming' value; and the potential to 'change the game' itself.

Parties

In the simplest negotiation, two principals negotiate with each other. Yet potentially complicating parties such as lawyers, bankers, and other agents may be present as may multiple internal factions with very different interests. The crucial first step for an effective negotiation analysis is to map the full set of potentially relevant parties in the context of the decision processes.

Interests

The next step is to probe deeply for each relevant party's or faction's underlying interests and to assess their trade-offs carefully. When individuals or groups with different concerns constitute a negotiating 'side,' it is no longer in general possible to specify overall tradeoffs; however, carefully tracing which set of interests is ascendant according to the internal bargaining process of given factions may continue to provide insights. Raiffa (1982) offers an extended discussion of assessing trade-offs in negotiation, building on extensive work by Keeney and Raiffa (1976; Sebenius, 1992). This assessment is radically subjective in the sense that less-tangible concerns for self-image, fairness, process, precedents, or relationships can have the same analytic standing as the 'harder' or 'objective' interests such as cost, time, and quality that are common to traditional economic approaches.

It is often useful to distinguish the full set of the parties' underlying *interests* from the *issues* under negotiation, on which *positions* or stands are taken. The connections among positions on issues and interests are rarely simple. Sometimes a focus on deeper interests can unblock a stubborn impasse over incompatible positions that relate only partially to the parties' real concerns. For example, the nominal issue under negotiation may be the base salary amount with incompatible positions (the boss says lower while the employee demands higher). Yet if the employee seeks a salary boost to pay for advanced technical training (an interest), the boss may realize that providing such training directly could be cheaper and in the company's interest as well. In other cases, emphasizing interests will only generate hopeless conflict when mutually beneficial agreement on certain overt positions could be reached.

Alternatives to Negotiated Agreement

People negotiate in order to satisfy the totality of their interests better through some jointly decided action than they could otherwise (typically by unilateral action such as shifting to an

alternative supplier, going to court, or striking). Thus, for each side, the basic test of a proposed joint agreement is whether it offers higher subjective worth than that side's best course of action absent agreement. In examining a negotiation, one should analyze each party's perceptions of its own – and the others' – valuations of their alternatives to negotiated agreement.

Alternatives to agreement may be certain, with a single attribute: an ironclad competing price quote for an identical new car. They may be contingent and multiattributed: going to court rather than accepting a negotiated settlement can involve uncertainties, trial anxieties, costs, time, and precedents that contrast with the certain, solely monetary nature of a pretrial accord. No-agreement alternatives may also involve potentially competing coalitions, threats, and counterthreats or the necessity to keep negotiating indefinitely. Various analytic tools from decision analysis to optimal search theory may aid in assessment of such alternatives (see Sebenius, 1992 for references).

While this evaluation provides a strict lower bound for the minimum worth (the 'reservation price') required of any acceptable settlement, alternatives to agreement also play tactical roles. The more favorably negotiators portray their best alternative course of action and willingness to 'walk away,' the smaller is the ostensible need for the negotiation and the higher the standard of value that any proposed accord must reach. Moves 'away from the table' that shape the parties' alternatives to agreement can strongly affect negotiated outcomes. Searching for a better price or another supplier, cultivating a friendly merger partner in response to a raider, or preparing an invasion should negotiations fail to resolve a contested issue, may influence negotiations more than sophisticated tactics employed 'at the table' such as clever opening offers or patterns of concession.

Representing the Structure

Imagine that two negotiators have thought hard about their underlying interests in different possible settlements of the apparent issues. Further, suppose that they have a relatively clear, if possibly changing, assessment of their trade-offs and have compared them to the value of their best no-agreement alternatives. Each has a sense of any 'rules of engagement' that structure their interaction. From the viewpoint of each party, a set of possible agreements has been envisioned. Assume that an analyst was privy to the results of these evaluations by each side, along with the (likely asymmetric) distribution of information about interests, beliefs, no-agreement options, and possible actions; these evaluations need not be common knowledge of the parties. The situation might be familiarly represented as in Figure 1.

The origin represents the value of failing to reach agreement: each side's best alternative to agreement implies the location of this point. The 'Pareto frontier' in the northeast part of the graph represents the evaluations of the set of those possible agreements on the issues that could not be improved on from the standpoint of either party without harming the other. In general, neither side knows the location of the frontier, only theoretically that it is there. The entire shaded region – bounded by the two axes and the frontier – is the 'zone of possible agreement.' In general, each party has its own

Figure 1 Representation of the zone of possible agreement.

perceptions of it. (In a purely distributive bargain, with no room for joint gains beyond the fact of agreement, the shaded region would collapse to a diagonal frontier along which better terms for one party imply worse terms for the other – even though both parties prefer such deals to impasse.) Since this representation is quite general, it can in principle encompass the whole range of possible interests, alternatives, and agreements.

From Structure to Outcome: Favorable Changes in the Perceived Zone of Possible Agreement

This is the point at which game-theoretic and negotiation analytic approaches tend to diverge. A game theorist would typically tighten the above specification of the situation, presume common knowledge of the situation and strategic rationality of the parties, and, by invoking a rigorous concept of equilibrium, investigate the predicted outcome(s) of the interaction. Indeed, as Rubenstein's insightful commentary noted, "for forty years, game theory has searched for the grand solution" that would achieve a

> prediction regarding the outcome of interaction among human beings using only data on the order of events, combined with a description of the players' preferences over the feasible outcomes of the situation.
>
> 1991: p. 923

Even with as powerful and ubiquitous a concept as that of the Nash equilibrium in noncooperative games, however, it is often impossible, even with the imposition of increasingly stringent requirements or refinements to limit a game's equilibrium outcomes to a unique or even small number of points. Often there is an infinitude of such outcomes. As Tirole noted when explaining why "we are now endowed with nearly a dozen refinements of perfect Bayesian equilibrium," the

> leeway in specifying off-the-equilibrium-path beliefs usually creates some leeway in the choices of equilibrium actions; by ruling out some potential equilibrium actions, one transforms other actions into equilibrium actions.
>
> 1988: p. 446

Frequently this implies an infinite number of perfect Bayesian equilibria.

Despite insights into how rational players might select from among multiple Nash equilibria (Harsanyi and Selten, 1988), the rationale for a particular choice may ultimately seem arbitrary. As Kadane and Larkey remark,

> we do not understand the search for solution concepts that do not depend on the beliefs of each player about the others' likely actions, and yet are so compelling that they become the obvious standard of play for all those who encounter them.
>
> 1982: pp. 115–116

This seems especially apt in light of their observation that "solution concepts are a basis for particular prior distributions" and hence

> the difficulty in non-zero sum, N-person game theory of finding an adequate solution concept: no single prior distribution is likely to be adequate to all players and all situations in such games.
>
> 1982: pp. 115–116

Since each party should accept any settlement in the zone of possible agreement rather than no agreement, Schelling (1960) made the potent observation that the outcome of such a situation could only be unraveled by a 'logic of indeterminate situations.' Without an explicit model or formal theory (equilibrium-based or other) adequate to map structure and tactics onto bargaining outcomes with confidence, how can an individual negotiator or interested third party decide what to do? In the (often implicit) view of many negotiation analysts, the negotiator's subjective distribution of beliefs about the negotiated outcome conditional on using the proposed tactics must be compared with his subjective distribution of beliefs about the outcome conditional on not using them. The tactic is attractive if the former distribution gives him higher expected utility than the latter.

Such 'improvement' has a subjective basis analogous to the Rothschild and Stiglitz (1970) characterization of a subjectively perceived 'increase' in risk. Specifying these distributions may require an internalized and subjective model of the bargaining process, since no such general model exists; where there is a well-developed and applicable game-theoretic model, of course, it should be used. Of course, the 'better' the empirical and theoretical basis for the assessment, the 'better' the subjective distributions of outcomes.

Much negotiation analytic work consists in improving the basis for assessing such outcome distributions. To do this, analysts pay attention to the special structure and dynamics that derive from the joint decision-making among parties, some of whom may be 'boundedly' rational.

Improving the Basis for Assessing Outcome Distributions I: Fundamental Processes of Negotiation

At bottom, negotiation processes involve both (1) actions to enhance what is jointly possible through agreement ('creating value') and (2) actions to allocate the value of agreement ('claiming value').

1. *Creating Value*. In most negotiations, the potential value of joint action is not fully obvious at the outset. 'Creating value' – that is, reaching mutually beneficial agreements, improving them jointly, and preventing conflict escalation – requires an approach often associated with 'win–win,' 'integrative,' or 'variable sum' encounters: to share information; communicate clearly; be creative; and productively channel hostilities. Yet regardless of whether one adopts a cooperative style or not, it is useful to have an analytic guide as to the underlying substantive bases for joint gains and how to realize them by effective 'dealcrafting.'
   First, apart from pure shared interests, negotiators may simply want the same settlement on some issues. Second, where economies of scale, collective goods, alliances, or requirements for a minimum number of parties exist, agreement among similar bargainers can create value. Third – and most interestingly – though many people instinctively seek 'common ground' and believe that 'differences divide us,' it is often precisely the differences among negotiators that constitute the raw material for creating value. Each class of difference has a characteristic type of agreement that makes possible its conversion into mutual benefit. For example, differences in relative valuation suggest joint gain from trades or from 'unbundling' differently valued attributes. Differences in tax status, liquidity, or market access suggest arbitrage. Complementary technical capacities can be profitably combined. Probability and risk aversion differences suggest contingent agreements or bets. Differences in time preference suggest altering schedules of payments and other actions. Sebenius (1984) formally characterizes such optimal betting, risk sharing, and temporal reallocations. Much work on optimal contracting (e.g., Hart, 1995) as well as classical economic study of gains from trade and comparative advantage directly bear on the kinds of agreements that create value on a sustainable basis. Sebenius (1992) and Lax and Sebenius (2002, 2006) offer extensive illustrations of these 'dealcrafting' or 'deal design' principles in practice.
2. *Claiming Value*. Crucial aspects of most negotiations, however, are primarily 'distributive,' 'win–lose,' or 'constant-sum,' that is, at some points in the process, increased value claimed by one party implies less for others. Several broad classes of tactics used for 'claiming value' in these kinds of bargains have been explored (e.g., Schelling, 1960; Walton and McKersie, 1965; Raiffa, 1982; Lax and Sebenius, 1986, 2006). Such tactics include: shaping perceptions of alternatives to agreement; making commitments; influencing aspirations; taking strong positions; manipulating patterns of concessions; holding valued issues 'hostage'; linking issues and interests for leverage; misleading other parties; and exploiting cultural and other expectations. By means of these tactics, one party seeks advantage by influencing another's perceptions of the zone of possible agreement.

Managing the Tension between Creating and Claiming Value: *The Negotiators'* Dilemma

In general, the benefits of cooperation are not fully known at the outset of a negotiation. Colloquially, the parties often do not know how large a value pie they can create. The way in which they attempt to expand the pie often affects its final division, while each side's efforts to obtain a larger share of the pie often prevents its expansion in the first place – and may lead to no pie at all, or even to a fight. Conclusion: creating and claiming value are not in general separable processes in negotiation. This fact undermines much otherwise useful advice (that, for example, presumes 'win–win' situations to have no 'win–lose' aspects, or 'integrative' bargains to be unrelated to 'distributive' ones).

Each negotiating party tends to reason as follows: if the other parties are open and forthcoming, I can take advantage of them and claim a great deal of value; thus I should adopt a value-claiming stance. By contrast, if the other parties are tough and adopt value-claiming stances, I must also adopt such a stance in order to protect myself. Either way, a strong tendency operating on all parties drives them toward hardball. Since mutual hardball generally impedes value creation, competitive moves to claim value individually often drive out cooperative moves to create it jointly. Outcomes of this dynamic include poor agreements, deadlocks, and conflict spirals. This tendency, closely related in structure to the famous Prisoner's Dilemma, was dubbed the 'Negotiator's Dilemma' (Lax and Sebenius, 1986: Chapters 2 and 7). Much negotiation advice is aimed at productively managing the inherent tension between creating and claiming value, especially to do so on a sustainable basis (Lax and Sebenius, 1981; Raiffa, 1982).

Improving the Basis for Assessing Outcome Distributions II: Behavioral Insight

A fully rational 'baseline' analysis helps to understand the possible responses of a rational other side. Urging consistent, if not fully rational, behavior on the subject of one's advice is often wise. After all, well-structured, repeated negotiations may penalize departures from rational behavior. Yet many negotiating situations are neither well-structured, repeated, nor embedded in a market context. While negotiators normally exhibit intelligent, purposive behavior, there are important departures from the 'imaginary, idealized, superrational people without psyches' (Bell et al., 1988: p. 9) needed by many game-theoretic analyses.

Considerable empirical work – such as that cited above by Bazerman, Neale, Thompson, and their colleagues – offers considerable insight into how people actually behave in negotiations. Excellent reviews of the psychological side of negotiation can be found in Bazerman et al. (2000a) and, focusing especially on developments on the social psychological side, in Bazerman et al. (2000b). Complementing this work is the burgeoning research in experimental economics (Kagel and Roth, 1995) and what Colin Camerer (1997) described as a 'behavioral game theory.' This work blends game-theoretic and psychological considerations in rigorous experimental settings. Two related levels are consistently important, the individual and the social:

1. *Individual negotiating behavior*. As negotiators, people have different histories, personalities, motivations, and styles. Systematic characteristics of individual cognitive processes can both help and hinder the process of reaching agreement. For example, negotiators may be anchored by irrelevant information, subject to inconsistencies in the way they deal with uncertainty, hampered by selective perception, obsessed by sunk costs and past actions, prone to stereotyping and labeling, susceptible to influence tactics and manipulation by the way in which equivalent situations are framed, liable to see incompatible interests when joint gains are possible, and use a variety of potentially misleading heuristics to deal with complexity, ambiguity, and conflict.
2. *Social behavior in negotiation*. In groups of two or more, especially where there is some perceived conflict, a variety of social psychological dynamics come into play that may enable or block negotiated outcomes. For example, a powerful norm toward reciprocity operates in most groups and cultures. Tentative cooperative actions by one side can engender positive reactions by the others in a cycle that builds trust over time. By contrast, social barriers can involve aspects of the interactive process that often lead to bad communication, misattribution, polarization, and escalation of conflict, as well as group dynamics that work against constructive agreements. Such dynamics may be especially pronounced when negotiations involve players of different genders, races, or cultures. Group dynamics can involve pressures for conformity, a hardening of approach by a representative before an 'audience' of constituents, bandwagon effects, and the individual taking cues from the behavior of others to decide on appropriate actions in the negotiation.

This experiment-based work is developing an empirical grounding for the behavioral basis of much a priori theorizing in economics and game theory. For negotiation analysis, these experimental approaches to actual behavior help to remedy a key defect of prior game-theoretic work. While for the most part not prescriptively framed (but see Malhotra and Bazerman, 2008), this body of work also provides rigorous evidence and theory on how people in fact are likely to behave – to inform assessments of outcome distributions and against which to optimize as appropriate.

Changing the Game

Much existing theory proceeds from the assumption of a well-specified and fixed situation within which negotiation actions are taken. Yet purposive action on behalf of the parties can change the very structure of the situation and hence the outcomes. Often actions can be understood as a tacit or explicit negotiation over what the game itself will be. First investigations into this phenomenon gave rise to the terms 'negotiation arithmetic' or 'adding' and 'subtracting' issues and parties (Sebenius, 1984). This means that a perfectly legitimate and potentially valuable form of analysis may involve a search for ways to change the perceived game – even though the menu of possibilities may not be common knowledge.

Issues can be linked or separated from the negotiation to create joint gains or enhance leverage. Parties may be 'added' to a negotiation to improve one side's no-agreement alternatives, as well as to generate joint gains or to extract value from others. Though perhaps less commonly, parties can also be 'subtracted' – meaning separated, ejected, or excluded – from larger potential coalitions. For example, the Soviets were excluded from an active Middle East negotiating role in the process leading up to the Camp David accords that only involved Israel, Egypt, and the United States. The process of choosing, then approaching and persuading others to go along may best be studied without the common assumption that the game is fully specified at the outset of analysis; Sebenius (1996) dissects and offers many examples of the process sequencing to build or break coalitions. Walton and McKersie (1965) focused on how negotiators seek to change perceptions of the game by what they called 'attitudinal restructuring.' Similarly, Lax and Sebenius (2006) systematically analyze many classes of purposeful changes in the 'setup' of a negotiation. In the context of competitive strategy and thinking, Brandenburger and Nalebuff (1996) develop a powerful, analogous logic for 'changing the game' that provides an overall approach and many ingenious examples of this phenomenon.

Refer back to **Figure 1**, an improvement in Player 1's no-agreement alternative shifts the vertical axis to the right, leaving the bargaining set generally more favorable to that side. If Player 2's no-agreement alternative worsens, the horizontal axis shifts down, worsening its prospects. A successful commitment to a bargaining position cuts off an undesired part of the zone of possible agreement for the party who makes it. A new, mutually beneficial option (e.g., suggestion of a contingent, rather than an unconditional, contract) causes the frontier to bulge upward and to the right, reducing the parties' 'conflict of interest.' When issues change or other basic aspects of the game vary, each side's perceptions of the basic picture in **Figure 1**, the zone of possible agreement, will be transformed. These possibilities add evolutionary elements to the analysis.

The Approach as a Whole

Figure 1 can now be seen to summarize visually the extended negotiation analytic 'model' of possible joint action. Parties determine the axes; interests provide the raw material and the measure; alternatives to agreement imply the limits; agreements hold out the potential. Within this configuration, the process consists of creating and claiming value, which gives rise to characteristic dynamics; yet, the elements of the interaction may themselves evolve or be intentionally changed. In this sense, the elements of the approach form a logically consistent, complete whole oriented around perceptions of the zone of possible agreement.

In the skeptical view of Harsanyi, this negotiation analytic approach might boil down to

> the uninformative statement that every player should maximize expected utility in terms of his subjective probabilities without giving him the slightest hint of how to choose these subjective probabilities in a rational manner.
>
> 1982

Yet, as described above, distinct classes of factors have been isolated that appear to improve subjective distributions of negotiated outcomes. Understanding the dynamics of creating and claiming value can improve prescriptive confidence. Psychological considerations can help as can cultural observations, organizational constraints and patterns, historical similarity, knowledge of systematic decision-making biases, and contextual features. Less than full-blown, game-theoretic reasoning can offer insight into strategic dynamics as can blends of psychological and game-theoretic analysis. When one relaxes the assumptions of strict, mutually expected, strategic sophistication in a fixed game, Raiffa's conclusion is appealing: that some "analysis – mostly simple analysis – can help" (1982: p. 359).

Conclusions and Further Directions

Naturally, there are many other related topics ranging from game-theoretic concepts of fairness for purposes of mediation and arbitration to various voting schemes. More elaborate structures are under study. For example, where negotiation takes place through agents, whether lawyers or diplomats, or where a result must survive legislative ratification, the underlying structure of a 'two-level game' is present (see Putnam, 1988). Negotiations also take place in more complex multilevel and coalitional structures (Raiffa, 1982; Lax and Sebenius, 1986, 1991; Sebenius, 1996). In many cases, the individual negotiation is not the appropriate unit of analysis. Instead, the study of 'negotiation design' – for example, of international conferences, alternative dispute resolution procedures, grievance negotiation processes – as well as analysis of multifront 'negotiation campaigns' seeks to maximize the chances of constructive outcomes from different structures and processes (Sebenius, 1991, 2010; Lax and Sebenius, 2012).

While game theorists and behavioral scientists will continue to make valuable progress in understanding negotiation, a complementary prescriptive approach has been developing that conditions its prescriptions on the likely behavior of the other side, fully 'rational' or not, and regardless of whether the 'game' is fixed and entirely common knowledge. In describing the logic of negotiation analysis and the concepts and tools that can facilitate it, this discussion has not stressed the many useful ideas that arise from focusing on interpersonal and cultural styles, on atmosphere and logistics, on psychoanalytic motivation, on communication, or on other aspects. Yet because the logic is general, it can profitably accommodate insights from other approaches as well as from experience. The basic elements of this logic – parties' perceptions of interests, alternatives, agreements, the processes of creating and claiming value, and changing the game – become the essential filters through which other factors must be interpreted for a meaningful assessment of the zone of possible agreement and its implications for the outcome.

This article is a revision of the previous edition article by N. Carmon, Volume 15, pp. 10488–10494, © 2001, Elsevier Ltd.

Abstract

The article provides a brief summary of selected publications about neighborhood/s by scholars in the social and behavioral sciences as well as by urban planners and architects. Neighborhoods have been part of the human mode of life since the dawn of civilization. In spite of the current decreasing importance of distance, following the accelerated development of telecommunication, it seems that neighborhoods will continue to exist in the next decades and fulfill important social functions for many persons in at least some of their time on earth.

Introduction

The term neighborhood is rooted in the verb neighbor. 'To neighbor' has a double meaning: (1) to live in the vicinity of one another and (2) to be friendly, to render mutual favors or assistance (Webster, 1983). This double meaning expresses the essence of the neighborhood: continuous physical proximity among people together with some social attitudes, such as friendliness, and/or special behaviors, such as mutual assistance. A neighborhood is always a part of a town or city, a part that is defined through an agreement among its residents, regular users, and others in its vicinity regarding its borders and its special physical and social characteristics. Frequently, neighborhoods are not officially defined and not everybody agrees about the size and borders of a neighborhood or its special identity.

This article is a brief summary of scientific and professional writings of the twentieth century about neighborhood/s by scholars in the social and behavioral sciences and by planners and architects. Its last section is devoted to contemporary discussions that shape the research of neighborhoods at the beginning of the twenty-first century.

The Neighborhood Concept in the Social Sciences

Neighborhoods have been considered by many scholars as a basic pattern of social organization, which is universal and timeless. Cooley (1909) argued that the neighborhood is 'a natural phenomenon' that exists wherever a group of people produce a dwelling place. Archeologists identified clusters of living that may be considered neighborhoods in kingdoms of the ancient world. The ancient neighborhoods were arranged by family or clan lines and later on, by religious, ethnic, or professional lines. In modern times, the divisions are largely by cultural–ethnic origin and/or socioeconomic status.

Neighborly relations among people who live in each other's vicinity, including intimate acquaintance and numerous interactions, were the normal way of life in rural communities prior to the industrial era (Tonnies, 1887). Sociologists of the early twentieth century, especially those from the Chicago school, claimed that such *primary relations* among neighbors are essential for maintaining the social order, because they create an effective informal control system (Cooley, 1909; Park et al., 1925). According to this view, isolation from a neighborhood portends an individual's alienation, while disintegration of neighborhoods threatens the social order (Durkheim, 1893).

The socioeconomic process of urbanization, which followed the technological-economic process of industrialization, disrupted social cohesion in rural communities and entailed the creation of distressed neighborhoods in the industrial cities. Among the first to describe them were Fredric Engels (1844), who demarcated the physical structures and daily life in Manchester and Salford in the United Kingdom, and Jacobs Riis (1890), who illustrated depiction of New York City's slum neighborhoods. The urban way of life was considered by many writers as a source of evil. Wirth (1938) argued that the size, density, and heterogeneity that characterize cities create changes that reduce primary relationships, including neighborly relationships, and increase loneliness and social deviance. Wirth represents the nostalgic yearning for healthy village life and the antiurban tone that was prevalent among writers of his generation.

A kind of 'neutral' description of neighborhoods was presented in the first half of the twentieth century by the Chicago 'ecological school,' headed by Robert Park, Ernest Burges, and R.D. McKenzie. They applied concepts and principles derived from plant and animal ecology to the analysis of human communities (Park et al., 1925). Empirical, sociological, and anthropological studies of urban neighborhoods in the middle of that century portrayed a more diverse urban picture (Glass, 1948; Janowitz, 1952). Within large industrial cities the researchers found residential areas that were *Gemeinschaft*s by Tonnies's typology; the intimate spontaneous relationships between the neighbors in such areas were based on proximity as well as on kinship, ethnic identity, and/or sharing a work place or other common denominator. Gans (1962) provided a vivid analysis of the life of Italian-Americans in a Bostonian neighborhood; he described these people, who managed to preserve their special family life, peer groups, and communal institutions within the modern city of Boston, as 'urban villagers.' Jacobs (1961) claimed that the traditional neighborhood such as the one described by Gans has lost its meaning and function in the modern big cities, where the lively street, the quarter (~100 000 residents), and the city as a whole are the relevant units. Suttle (1972) argued that in the modern city, one can find various different types of

neighborhoods, from the ones that are based on a form of organization that is almost a primary group to expanded communities of 'limited liability.'

A special stream of research was devoted to the impact of architectural design on social attitudes and behavior in the neighborhood context. Researchers frequently found strong relationships between architectural design and social variables: proximity and planned paths seemed to influence close friendship (Festinger et al., 1950), while large project size and height of buildings were considered as causes of increased delinquency and crime (Newman, 1972). Later critics, who named this line of reasoning 'physical determinism,' claimed that these studies failed to control for important intermediate variables, especially those related to the sociocultural and the socioeconomic characteristics of the residents. Keller (1968) urged architects to tailor their design by the variety of socioeconomic characteristics and cultural values of the users.

In response to the unidirectional view on the influence of the built environment on people, the school of man–environment research, consisting mainly of psychologists who cooperate with architects, emphasizes a two-way man–environment interaction. Their ecological approach to human interaction centered on understanding individuals in the context of their surroundings (Barker, 1968) and allows for personal-subjective definitions of neighborhoods. According to this perspective, the neighborhood is considered as one of the contextual ecological systems that a person is part of, including the nuclear family, peer group, and workplace (Bronfenbrenner, 1979).

Thus, neighborhoods have been defined through consolidating both social and physical spaces, i.e., when physical boundaries, social networks, local facilities, and special symbolic and emotional connotations are congruent in people's mind (Rappoport, 1977). According to this approach, people relations with their neighborhood coevolve through a process in which a space is transformed into a 'place' – a setting with a specific meaning and value (Tuan, 1974). Emotions and other psychological and social mechanisms (i.e., belonging and identification, sense of community and social capital) play a role in the development of a neighborhood and at the same time influence the lives of individuals; one is constantly affected by the other. For example, physical conditions and opportunities for social interaction in the neighborhood affect personal attitudes such as satisfaction and identification with the neighborhood, which, in turn, play a role in residents' willingness to be involved and improve their neighborhood (Ahlbrandt, 1984).

In addition to their social and psychological roles, urban neighborhoods often function as administrative units for various ends, including political organization and provision of social and commercial services. For census purposes, residential areas are divided into statistical units, the borders of which are frequently drawn by the boundaries of traditional neighborhoods. Social scientists have made intensive use of this statistical division, especially for developing empirical social area analysis that concentrates on changes over time in residential areas (Shevky and Bell, 1955; Abu-Lughod, 1969).

Neighborhood change was a focus of interest of social scientists throughout the twentieth century. The Chicago school invented the invasion–succession model, inspired by the world of plant and animals; 'invasion' illustrates the entrance of a different social group – racially, ethnically, or socioeconomically different – to a populated area, and the creation of competition and conflict within the invaded neighborhood that ends either by withdrawal of the invaders or by their triumph in the form of 'succession' (Park et al., 1925). The study of neighborhood change flourished in the second half of the twentieth century. Taeuber and Taeuber (1965) produced a comprehensive study of racial neighborhood change in American cities. Several economists added a considerable amount of supporting empirical evidence, especially for explaining neighborhood deterioration (Grigsby et al., 1987). A review of the neighborhood change literature of the time was provided by Schwirian (1983).

Another model of neighborhood change – *the life cycle model* – was suggested by Hoover and Vernon (1959), who identified five stages: development, transition, downgrading, thinning out, and renewal. These stages are related to the quantity and status of the residents, the intensity and kind of land use, and the quality of housing. Not all neighborhoods go through each stage; some may skip one or stay indefinitely in another.

The *political economy school* offers a different approach. They argue that the fate of a neighborhood is determined by the interests and the complex relationships among the political and economic public institutions and the strong actors in the business market (banks, developers, and others). Most of these forces play from outside the borders of the neighborhood, and hence, the ability of local people to influence them is very limited (Molotch, 1976).

Neighborhoods in the Eyes of Planners and Architects

Modern urban planning took its shape in the last quarter of the nineteenth century on the background of the socioeconomic movements of industrialization and urbanization. Large populations of workers and their families lived in extremely poor and crowded conditions in the industrial cities. The first planned neighborhoods in Europe were workers' neighborhoods, built by owners of industrial plants or by philanthropic organizations.

All the early city planning initiatives – The City Beautiful, The City Efficient, and The Garden City – sought to make the city and its neighborhoods safe, sanitary, economically efficient, and socially attractive. The leading idea was to use physical planning in order to create a socially better world. This central motive accompanies the efforts of architects and planners throughout the twentieth century. Several critics say that this is clear evidence that good intentions may sometimes lead to hell.

A prominent figure from the onset was Ebenzer Howard; his small-size book, *Garden City of Tomorrow* (1902), influenced urban planning in the twentieth century more than any other publication. He advocated an urban environment that combines the advantages of the city, such as modern occupations and services, with those of the village – human scale and many local social contacts. His model covered the entire scale from the dwelling through the neighborhood to the region. Howard's ideas had a decisive

impact on the New Towns Movement, which gave rise in the middle of the twentieth century to 30 new towns in Great Britain, a similar number in Israel, several *villes nouvelles* around Paris, others around Stockholm, as well as a few new towns in the United States. Within each of these, some version of Howard's plan for the 'ward' (his version of a neighborhood) was implemented. However, none of the many towns and neighborhoods that followed Howard's physical suggestions (at least partly) followed his social vision. As Hall (1988: p. 87) put it: "They see him as a physical planner, ignoring the fact that his garden cities were merely the vehicles for a progressive reconstruction of capitalist society into infinity of co-operative commonwealths."

In the United States, a rather similar (physically) model for a neighborhood unit was proposed by Clarence Perry (1929). He suggested a design formula with specific guidelines for spatial distribution of residences, community services, roads, open spaces, and businesses; he believed in using physical design tools for achieving a social vision of neighborliness and community building. A strong supporter of the concept of the neighborhood unit was the journalist–sociologist Louis Mumford (1954). He saw neighborhood planning as an opportunity and leverage for fostering feelings of belonging and for supporting amiable behavior among neighbors. He contributed to the idealization of the neighborhood as a framework for preserving positive social values and institutions in the modern city. This idealization was among the factors that convinced the American Public Health Association to adopt the neighborhood unit model as the basis for planning residential environments. Subsequently, it was adopted by other professional organizations and public agencies and guided much of the post-World War II construction of middle-class suburbs. All this happened in spite of the severe criticism of the model that had been prevalent since the 1940s. Social scientists disagreed with its premises and planners questioned its unintended consequences (Banerjee and Baer, 1984). Even though theoretically the model called for social mix and social integration, in practice, it encouraged segregation. An example is the early settlement in the neighborhoods of the new town of Radburn (New Jersey, US); in 1934, there were no blue-collar workers among the residents, and the realtors kept out Jews and Blacks as well (Schaffer, 1982).

What was planned and built in the middle of the twentieth century in Europe was highly influenced by the architects of *Les Congres Internationaux d'Architecture Modern*, an organization that was established in 1928 and lived for 30 years (Kallus and Law-Yone, 1997). These architects were deeply influenced by rigid socialistic concepts on the one hand and by new technical options that opened up through the industrial advancement on the other. They created the international style of architecture with the principles of minimalism (planning a house by the minimal needs of health and convenience of the residents), standardization (disregarding differences of culture, climate, etc.), and separation of land uses. Le Corbusier was the most famous architect who promoted these concepts. Thousands of neighborhoods, which were built in Europe following World War II, were influenced by these principles. However, many of their inhabitants disliked the minimal and standard blocks that the architects built for them; better-off households left them as soon as they could afford it. The unattractive design, together with severe maintenance problems, played a central role in the processes of social and physical deterioration and segregation, which characterized large residential areas of the post-World War II residential construction in European and other countries (see Ch. 7 in Hall, 1988).

An architectural school that opposes the standardization of international architecture as well as the typical design of neighborhoods-suburbs in the United States is the *New Urbanism*. It developed in the 1980s, as an umbrella term that encompassed two design schemes: the traditional neighborhood development, actually, back to the neighborhood unit concepts, and the transit-oriented development. The common principles of these two are small (compact) size that creates walkable distances (typically no more than a quarter of a mile from center to edge), clearly defined edges and centers, mixed land uses (residences, shops, schools, and workplaces) and mixed 'market segments' and priority to public buildings and spaces (Katz, 1994). In some magic way, this design is expected to create not only a distinct physical unit but also social identity and community. Underneath the detailed design instructions of the New Urbanism lies the same old belief of architects that by means of proper design of the physical environment one can create a better social world.

In addition to a common belief in *physical determinism*, most of the neighborhood models suggested by architects are characterized by disregard of the users' voice. For Le Corbusier this was obvious; he argued that planning is too important to let ignorant people be involved in it. Other architects continued the paternalistic approach without considering issues of residents' participation. One of the exceptions was the English architect John Turner (1976), the father of 'housing as a verb' rather than a noun. He argued that when dwellers control the major decisions concerning the design, construction, and management of their home and neighborhood, both the process and the environment produced stimulate individual and social well-being. Turner based his approach on his experience with communities in which there was mutual commitment and partnership between the members, mostly traditional communities. Is consideration of users' point of view in designing and managing the built environment applicable also to regular neighborhoods in urban Western societies?

A positive answer to this question evolved within a new breed of planners. In the middle of the twentieth century, social scientists – sociologists, economists, human geographers, and lawyers with social sensitivity – transformed the discipline/profession of urban/city planning. The sociologist Herbert Gans (1968) played a central role in this process of change; years later, he phrased an important part of the transformation by saying that "America's major urban problems were poverty, scarcity of decent jobs, racism … more serious and wide-ranging than the land-use-related problems the city planners of the time were dealing with" (Gans, 1991: p. IX). Scholars and practitioners of urban planning developed the ideas and practices of citizen participation in planning and community development (Arnstein, 1969; Bratt and Rearden, 2013), of Advocacy Planning (Davidoff, 1965), Progressive Planning (Angotti, 1993), and Equity Planning (Krumholz and Forester,

1990; Carmon and Fainstein, 2013). All these frameworks of thought and action devoted much of their work to urban neighborhoods of minorities and low-income households.

The different approaches of planners who had only architectural education vis-à-vis those who were widely exposed to the social sciences were clearly expressed in the development of programs for rehabilitating distressed neighborhoods (Carmon, 1990). Three successive 'generations' of urban/neighborhood renewal policies were identified and analyzed by Carmon (1999), policies that were implemented at about the same time in Western countries on both sides of the Atlantic. The first generation – the era of the bulldozer, which was dominated by architects, by ideas of physical determinism and activities of slum clearance—started in the United Kingdom in 1930, in the United States in 1937 (see also the law of 1949), in Canada in 1948, and in several European countries in the 1950s. The slum clearance projects, in spite of big differences among them, usually generated the same kind of criticism for hurting individuals and households, eliminating healthy communities, and, in general, bringing about more negative than positive human and urban consequences (Wilmott and Young, 1957; Belash and Hausknecht, 1967; Gibson and Langstaff, 1982). In the second generation of policies, when urban planners with education of social sciences became influential, large-scale governmental programs for both social and physical neighborhood rehabilitation were adopted and citizen participation in planning became common; examples are Model Cities in the United States (mid-1960s), Neighborhood Improvement Program in Canada (started in 1973), Neighborhood Social Development in France (started in 1981), and Project Renewal in Israel (started in 1977). Despite the abundance of goodwill and large sums of money, the results were at best mixed: where implemented, these combinations of social and physical programs frequently benefited people (local residents) but not their neighborhoods, i.e., they could not change the negative image and the low status of the target neighborhoods. The third generation is related to the rise of the neoliberal ideology from 1970s to 1990s and emphasizes economic considerations in neighborhood and urban regeneration. Public–private initiatives of planned gentrification that encouraged better-off households to enter low-income neighborhoods, usually in the city center, became popular in many large and small cities. Many of those have physically improved parts of old cities and neighborhoods, but were severely criticized for causing direct and indirect displacement of incumbent residents (Marcuse, 1985; Smith, 2002).

Neighborhood Research on the Brink of the Twenty-First Century

We began this article by saying that neighborhoods have been part of the human mode of life since the dawn of civilization. An ancient verse – "better is a neighbor that is near than a brother far off" (Proverbs 27:10) – illustrates the important social functions that neighborhoods and neighbors had in traditional societies. With the development of communication technologies, people became much more mobile, their world widened considerably, and they became less dependent on physical proximity and on constant relationships. The decreasing importance of distance has been enhanced with the accelerated development of telecommunication in recent years. Do these changes mean that the time of neighborhoods as territories that combine physical and social closeness is over?

The answer is that neighborhoods will continue to exist in the next decades and fulfill important social functions for many persons in at least some of their time on earth. In general, those who are attached to their neighborhoods are people on the ends, on both ends of the life cycle – children and elderly, and on both ends of the social ladder – disadvantaged and well-to-do households. People whose mobility is limited, either because modern communication technologies have not reached their environment, or because they are too young, too old, or too poor to use the technologies, will continue to be dependent on their neighbors and neighborhoods as sources for fulfilling functional as well as social and emotional needs. In addition, research findings show that housing proximity is associated with the existence of important joint interests. This is very clear among minorities and immigrant groups, which tend to cluster geographically and create *urban enclaves*; in their enclaves, they can support each other; defend and develop their specific social, economic, and sometimes political interests; and when they feel necessary, can organize to fight contradicting interests (Abrahamson, 1996). This is also common among exclusive neighborhoods of affluent citizens who create gated communities (Blakely and Snyder, 1997; Atkinson and Blandy, 2005). Mobile middle-class households may not be inclined to be part of neighborhoods-communities, but where and when they feel a need to promote a local interest, and, especially, when some changes in the social or physical environment is perceived as a threat to the value of their home, they too function as a community of interests on a local basis.

Thus, in recent years, research into 'neighborhood effects' has become common; its point of departure is frequently an assertion that neighborhood characteristics play a significant role in shaping opportunities, quality of life, and social norms of their residents, especially immigrants and low-income residents. The current renewed interest in these effects is traced back to the book *The Truly Disadvantaged* (Wilson, 1987). Since its publication, an explosion of work has emerged testing the hypothesis that living in a neighborhood of concentrated poverty has negative effects on economic self-sufficiency, violence, drug use, low birth weight, cognitive ability, and more. Especially salient are the many studies devoted to evaluating the *Moving to Opportunity* housing mobility experiment (Briggs et al., 2010). In general, the findings have been disappointing; the move to better neighborhoods has not been found as having considerable positive effect on self-sufficiency or on physical health; yet, many claim that the failure was built into the implementation of the experiment and the research design (Sampson, 2008). Disappointing results regarding impacts on labor market outcomes were reported also from Britain (van Ham and Manley, 2010). However, research of other kinds of 'effects' did find positive ones: health researchers have found significant positive impacts of neighborhood characteristics on individual

physical and mental health (Diez Roux, 2004), especially among children and adolescents (Leventhal and Brooks-Gunn, 2000). Kim and Kaplan (2004) showed how neighborhood design features, new urbanism style, have direct and indirect effects on residents' sense of community. When the physical design of a neighborhood (Bothwell et al., 1998) and/or participation in neighborhood activity lead to development of social capital, especially 'bridging' social capital, the range of opportunities for disadvantaged residents is increased (Gittell and Vidal, 1998).

In the context of a globalizing world, researchers identified the two contrasting yet complementary components of the global and the glocal. Relevant examples are global marketing of neighborhoods to attract capital investment and residents of the creative class (Mele, 2000), and building bottom–up organizations to counter the top–down controls of global bodies. In general, it seems that the perceived importance of the local is gathering force in parallel with the global trend. Neighborhoods are sites for engagement of residents in the practice of planning their environment (Innes and Booher, 2004) and for establishment of active citizenship (Brannan et al., 2006) aiming at democratizing social relations and promoting social and environmental justice. In Europe, this orientation is implemented in local bodies through the 'new localism' (Lowndes and Sullivan, 2008), while the Community Development Corporations are continuing their activity across the country in the United States (Bratt, 2006), and the Local Agenda 21 is spreading around the world (RIO+20, 2012). The outburst of protests in 2011, protests that occurred at about the same time in close to a thousand cities in 82 countries (Rogers, 2011), is a demonstration of the current new relationships between local communities and global developments.

Because the local context of a neighborhood continues to play an important role in the life of many individuals and groups, social scientists will continue to be engaged with understanding neighborhoods in the foreseeable future. Following Herbert Gans (2002), the authors suggest focusing on causal relations between space/place and society: the few but important ways in which a place – a neighborhood in this case – influences persons and collectivities, and the many ways in which collectivities turn places into social spaces and shape their uses.

Neighborhood Effects

Jacob W Faber and Patrick Sharkey, New York University, New York, NY, USA

Abstract

Social scientists have long been concerned with the role of space in systems of stratification. While scholars in the field of 'neighborhood effects' have typically focused on how a community affects the life chances of its residents, we argue for a broader view of neighborhood effects that considers how spatial stratification serves to maintain and reproduce inequality across multiple dimensions. This article outlines major theoretical arguments exploring how local residential contexts affect social and economic outcomes at the level of individuals and communities, drawing attention to the empirical challenges to measuring neighborhood effects.

Introduction

The term 'neighborhood effects' has come to be associated primarily with research that considers how characteristics of communities affect the life chances of individuals within them. This strand of research represents only a narrow view of the role that residential settings play in systems of stratification, however. A long-standing tradition of research begins with the idea that systems of stratification are organized, in part, along spatial lines. The neighborhood, from this perspective, is a core dimension of inequality. Building on this assumption, we argue for a broader view of the neighborhood effects literature, one that includes all research attempting to move toward a more complete understanding of how spatial stratification serves to maintain and reproduce inequality across multiple dimensions.

This view of neighborhood effects research is difficult to summarize, and we do not attempt an exhaustive review. Instead, we describe some of the most common approaches to studying neighborhood effects, and we offer examples of research supporting our more expansive perspective. We begin with a focus on theoretical conceptions about the processes through which neighborhood inequality affects other dimensions of inequality. Next, we consider the challenges in moving from theory to empirical evidence on neighborhood effects, and we explore some of the evidence base pertaining to neighborhood effects on several domains of economic and social life. We conclude with a discussion of where advancements in data collection, methods, and theory may bring the field.

Theory and Mechanisms

The resurgent interest in the role of neighborhoods as a core dimension of stratification often is traced back to the publication of William Julius Wilson's *The Truly Disadvantaged* (1987). In this book, Wilson laid out a theory to explain the transformation of urban poverty in the post-Civil Rights era, and argued that the new concentration of poverty in central city neighborhoods helped explain changes in the prevalence of other social outcomes such as joblessness, teenage parenthood, welfare dependence, and violent crime (see also Sampson and Wilson, 1995). Wilson's theory is complemented by the research of Douglas Massey and several colleagues, who focused attention on the importance of racial segregation as the mechanism by which changes in economic conditions translate into concentrated poverty at the community level (Massey and Denton, 1993).

What is most notable about these arguments is their focus on the spatial organization of inequality and the consequences for urban phenomena and social outcomes at the community level. In most reviews of the literature, the ecological approach to neighborhood effects research receives less attention than research focusing on individual outcomes. However, Sampson (2003, 2006, 2012; Sampson et al., 2002) points to a long tradition of research on community organization, health, and violence in arguing that the ecological approach aligns most closely with classic sociological research on spatial stratification (for example, see Bursik and Grasmick, 1993; Shaw and McKay, 1942). Building on this tradition, Sampson et al. (1997) argued that the relationship between concentrated poverty and violence is mediated by community-level social processes arising from social cohesion, trust, and community organization (see also Sampson et al., 2002). This research is one example of a large body of work that considers the spatial organization of social, economic, and political phenomena and the consequences for community-level outcomes related to health, crime, violence, and well-being (Massey and Fischer, 2003; Sampson et al., 2002).

A larger set of theoretical mechanisms have been proposed as plausible ways in which neighborhoods may be linked to individual social and economic outcomes. In an early review of the empirical literature, Jencks and Mayer (1990) outlined several sets of mechanisms by which individuals' residential contexts (including both neighborhoods and schools) might affect resident outcomes in both positive and negative ways. *Epidemic models* focus on the ways that peers influence one another, *collective socialization models* focus on adult influence on children other than their own, and *institutional models* focus on how children's outcomes may be affected by neighborhood institutions. *Relative deprivation models* focus on how people see themselves in relation to people within and outside the community, *cultural conflict models* focus on the ways that groups create a common culture to deal with collective failure, and *competition models* posit conflict over scarce resources make affluent neighbors a liability.

Since the influential article by Jencks and Mayer (1990), other reviews of the literature have added nuance to the question of how growing up in a particular place might matter for individuals. Several of these articles argued that aspects of local context may have different effects across life stages. Ellen and Turner (1997), for example, suggested that infants and preschool children are most directly affected through parents, whereas schools become increasingly relevant for elementary school-aged children. Leventhal and Brooks-Gunn (2000) argued that environmental pollution may have a stronger effect on an individual in earlier stages of development. Ellen and Turner (1997) and Small and Newman (2001) argued that social life within the residential environment may have the greatest influence on the lives of adolescents, who are at risk of becoming involved in risky behaviors or activities through their peers and role models in the community. For adults, neighborhood effects may operate through the prevalence of services, information, social networks, and employment opportunities (Ellen and Turner, 1997; Small and Newman, 2001).

As the empirical literature has evolved and expanded, so too have theoretical models of mechanisms by which the local residential context could potentially shape individual outcomes. Recent contributions argue that neighborhood effects should be viewed as an interaction between the duration of exposure to neighborhood characteristics and the vulnerability of the individual exposed (Galster, 2012; Harding et al., 2011; Small and Feldman, 2012). Incorporating these ideas into empirical studies of neighborhood effects allows for a distinction between an individual who, for example, spent her entire childhood in a high-poverty neighborhood and another who only experienced a brief period of exposure. Similarly, this more refined approach suggests that neighborhoods should be operationalized at different scales depending on the specific exposure or process under study (Galster, 2008; Logan, 2012; Sampson et al., 2002). Whereas the school catchment area may be most relevant for understanding children's academic success (Schwartz, 2010), shocks in the demand for labor over a wider geographic area may be more relevant for understanding the effects of the residential setting on economic outcomes (Ananat et al., 2011; Jargowsky, 1997).

From Theory to Evidence

There are several challenges to translating theories of neighborhood effects into persuasive evidence, but virtually every review of the empirical literature on neighborhood effects has focused primary attention on the problem of selection bias (Ellen and Turner, 1997; Jencks and Mayer, 1990; Leventhal and Brooks-Gunn, 2000; Ludwig et al., 2008; Sampson et al., 2002). The challenge of selection bias arises because families may end up in disadvantaged neighborhoods due to a range of unmeasured factors that are likely to be correlated with key outcomes of interest, and the magnitude and direction of this bias often are unclear (Ludwig et al., 2008).

Several approaches have been used to confront selection bias in the neighborhood effects literature. Sampson et al. (2008), for example, took advantage of rich data on family characteristics typically not measured in survey data to develop more refined models for selection into advantaged and disadvantaged neighborhoods in Chicago, and used these models to estimate the effect of exposure to concentrated disadvantage on cognitive development. Harding (2003) used a propensity score-matching approach to estimate the effect of neighborhood poverty on high school dropout and teenage pregnancy, combined with a sensitivity analysis to assess how robust estimates were in the presence of potential confounders (see also Sharkey and Elwert, 2011). Several studies have used family fixed effects methods or sibling and neighbor correlations to identify the effect of neighborhood conditions on educational and economic outcomes (e.g., Aaronson, 1998; Page and Solon, 2003; Plotnick and Hoffman, 1999; Vartanian and Buck, 2005). These approaches typically rely on variation in neighborhood conditions among siblings within the same families, and thus account for unobserved, stable characteristics of families that are shared by all siblings.

Whereas all of the empirical approaches discussed to this point rely on variation in neighborhood conditions derived from the residential choices of families, an alternative set of methods rely on variation derived from natural experiments, or controlled experiments, that lead families into different residential settings. As an example, Kirk (2009) leveraged displacement caused by Hurricane Katrina as a natural experiment that affected the geographic locations to which Louisiana state prisoners returned in the aftermath of the hurricane, and found that prisoners forced to move to a community other than that from which they originated had lower rates of subsequent incarceration. The more common approach is to exploit variation in neighborhood conditions arising from experimental or quasi-experimental residential mobility programs. The first example of this form of research came about in the aftermath of a court desegregation lawsuit. The Gautreaux Assisted Housing Program was the result of a settlement that required the Chicago Housing Authority to provide housing to eligible families in neighborhoods across the entire Chicago metropolitan area, including affluent and predominantly white suburbs. Early research found that families that moved outside Chicago's city limits experienced remarkable changes in adults' economic outcomes and children's educational attainment (Rubinowitz and Rosenbaum, 2000). Subsequent analyses of families in the Gautreaux program have documented problems with the original studies and with the overall research design; however, after adjusting for observed differences between families in the program, virtually all of the research that has been conducted on Gautreaux has found that families benefited substantially when they left the deeply segregated, high-poverty neighborhoods of Chicago and moved to more integrated, less-poor communities (Mendenhall et al., 2006; Votruba and Kling, 2009).

The Moving to Opportunity (MTO) Program was a federally funded social experiment implemented specifically to test whether moving into low-poverty neighborhoods affected the social and economic outcomes of families living in five cities (Baltimore, Boston, Chicago, Los Angeles, and New York) (Goering and Feins, 2003). In each city, families that volunteered for the program were randomized into one of three groups: an experimental group that received housing vouchers that could only be used to rent in low-poverty neighborhoods; a group that received standard Section 8

vouchers without requirements on where the voucher could be used; and a control group that received no voucher at all. Initial evaluations of MTO were mixed (Ellen and Turner, 2003; Ludwig et al., 2008; Sampson, 2008). Ten to fifteen years after random assignment, parents in the experimental group reported substantial improvements in mental and physical health and overall well-being, but no improvements in economic outcomes (Ludwig et al., 2011). Treatment effects on children varied substantially by gender. Girls in the experimental group showed improved mental health and were less likely to participate in some risky behaviors, whereas boys experienced an increase in some risky behaviors and no changes in other indicators of successful development (Sanbonmatsu et al., 2006).

Interpreting the results from MTO is challenging because the study was conducted at a unique historical moment when employment opportunities were expanding very quickly in central city neighborhoods, public housing projects were being torn down in many cities, and violent crime was dropping rapidly (Sharkey, 2013). The experimental treatment provided a short-term change in families' neighborhood environments that faded away for most families. For instance, 10–15 years after random assignment, families in the experimental group lived in neighborhoods with poverty rates just 3% points lower than families in the control group (Ludwig et al., 2012). This feature of the experiment is highly relevant to interpreting the results, as Turner et al. (2012) showed that families that remained in low-poverty neighborhoods for longer periods of time experienced meaningful improvements in outcomes across multiple domains. Further, the experiment played out very differently across the five sites where it was implemented (Briggs et al., 2010), with children in some cities experiencing substantial improvements in developmental outcomes and children in other cities showing null results (Burdick-Will et al., 2011).

Analyses of other quasi-experimental residential housing programs have generated results that are complex, with results that vary depending on where the program was conducted, the type of change in housing and neighborhood conditions induced by the program, and the outcome under study. In Montgomery County, MD, for example, Schwartz (2010) exploited the random assignment of public housing recipients to units that fall within a wide range of school catchment areas. Her analysis found that children falling within the boundaries of lower-poverty schools outperformed children assigned to housing in higher-poverty areas on math and reading tests. In Denver County, CO, low-income families were offered housing via the 'Dispersed Housing Program' when they reached the top of a waiting list. Cutsinger et al. (2011) argued that this process created exogenous variation in the units offered to families, and found that residence in neighborhoods with higher crime, lower homeownership rates, and lower levels of social capital were linked with lower rates of high school graduation. Ludwig et al. (2010) also use data from families on a wait list for subsidized housing in Chicago to estimate the effects of change in neighborhood conditions on standardized test performance. Families were randomly assigned a number on the wait list for housing, which created exogenous variation in the timing of when families were able to move into new apartments in lower-poverty neighborhoods than those from which they came. The researchers found that moving into lower-poverty neighborhoods resulted in substantively large improvements in children's performance on reading and math assessments. Carlson et al. (2012) also leveraged a waiting list process and used propensity scores to match Section 8 recipients in Wisconsin to similarly situated social service recipients who did not receive housing support. While those receiving vouchers moved to somewhat improved neighborhoods, this neighborhood change did not translate into improved economic circumstances on average – there was little effect on unemployment and a negative effect on earnings that faded over time. However, more vulnerable participants (i.e., those with less education and minorities) showed better labor market outcomes. Massey et al. (2013) analyzed the effects of neighborhood change resulting from the court-mandated construction of affordable housing in the relatively affluent Philadelphia suburb of Mt. Laurel. Using propensity scores to match program participants to those on the waiting list who were not offered housing, they found that those who moved had higher earnings and employment rates than those who did not, although there was no effect on welfare receipt. In contrast to the Wisconsin Section 8 study, movers with more education experienced greater economic benefits.

Although the problem of selection bias has received the greatest amount of attention in the literature, it is only one of many challenges to the identification of unbiased neighborhood effects. Disentangling the effects of the neighborhood setting from the effects of family characteristics is extremely difficult in observational studies because family circumstances and neighborhood conditions are reciprocally related over the life course and over generations of family members (Jencks and Mayer, 1990; Sharkey and Elwert, 2011). Identifying the specific dimension of the residential environment that is most salient for a given individual or ecological outcome is challenging because of the way that different dimensions of spatial advantage and disadvantage come bundled together in the neighborhood setting (Jencks and Mayer, 1990; Ludwig et al., 2008). Sampson (2008) argued that estimates of neighborhood effects from observational studies may be biased toward zero because of 'included variable bias,' which arises in studies where controls are added that may represent mechanisms by which neighborhoods affect individual outcomes. For example, if neighborhood conditions affect mental or physical health (Klebanov et al., 1994; Ludwig et al., 2011; Wheaton and Clarke, 2003), then estimating neighborhood effects while adjusting for parental health will lead to overly conservative, biased estimates.

Experimental studies of neighborhood effects are not immune to problems of identification (Sampson, 2008). Estimates derived from experimental residential mobility programs such as the MTO rely on the assumption that families in the treatment and control groups are isolated from each other and have no interactions that may 'contaminate' the estimated treatment effect of the program (Ludwig et al., 2011; Sampson, 2008; Sobel, 2006). Most empirical studies of neighborhood effects, whether observational or experimental, make the implicit assumption that the impact of the neighborhood is linear (Jencks and Mayer, 1990). This assumption is

questionable from both a theoretical standpoint and an empirical standpoint (Crane, 1991). For example, research exploiting variation across the five sites where the MTO program was implemented found that youths from the most intensely disadvantaged neighborhoods (i.e., Baltimore and Chicago) may have benefited most from the intervention, a finding that is suggestive of nonlinear neighborhood effects (Burdick-Will et al., 2011; see also Klebanov et al., 2014).

Various neighborhood risk factors may also work in concert with other neighborhood and individual characteristics to have the most detrimental effect on outcomes of interest, presenting additional empirical challenges (Evans and Kantrowitz, 2002; Jencks and Mayer, 1990). For example, numerous studies have documented substantial differences in neighborhood effects by gender. Women and girls face unique risks in high-poverty, violent neighborhoods (Popkin et al., 2008), which may make them more responsive to changes in the local residential setting (Clampet-Lundquist et al., 2011; Elliott, 2001; Kling et al., 2005; Miller, 2008; Sanbonmatsu et al., 2006; Zimmerman and Messner, 2010; Zuberi, 2012). The evidence is less conclusive regarding differences in neighborhood effects across economic strata (Ananat et al., 2011; Massey et al., 2013; Wodtke et al., 2012) or racial/ethnic groups (Crosnoe, 2009; Crowder and South, 2003; Sanbonmatsu et al., 2006; Turley, 2003). Similarly, while there is not a consistent pattern in the research on differences in neighborhood effects by age (Ananat et al., 2011; Sharkey et al., 2013; Wodtke et al., 2012), negative consequences may compound over the life course. For example, people born into disadvantaged communities not only start life at lower weight (Morenoff, 2003), but experience sharper, unhealthy increases in body mass index as young children (Klebanov et al., 2014).

Beyond the problem of identification, the neighborhood effects literature has struggled with challenges of measurement. The most common approach to measuring neighborhood characteristics is to define the neighborhood through administrative boundaries, typically the census tract, and to measure aggregate characteristics of the population within the boundary, such as the poverty rate (Sampson et al., 2002). Compositional characteristics of census tracts such as poverty, economic inequality, racial and ethnic composition, class composition, and unemployment are all derived from this approach to the operationalization of neighborhoods. Although this is the default approach to studying neighborhood effects, it is important to acknowledge that many theoretical models described in the previous section of this article do not align well with this approach to operationalizing the neighborhood (see, for instance, Burton et al., 1997; Durlauf, 2004; Rosenblatt and DeLuca, 2012).

Research on institutions such as schools, for example, has used school catchment areas as the relevant boundary for studying the link between school quality and academic achievement (Schwartz, 2010). Research exploring environmental pollution has used proximity to sources of air pollution or noise pollution to understand how these aspects of the environment influence individual or aggregate outcomes of children (Bronzaft and McCarthy, 1975; Cohen et al., 1980; Currie et al., 2009; Downey and Van Willigen, 2005; Evans, 2006; Evans and Maxwell, 1997; Hambrick-Dixon, 1985; Ransom and Pope, 1992; Stansfeld et al., 2005). Studies of economic shocks have measured changes in labor markets across wider spatial scales, such as counties or Native American reservations, to study the effect of such shocks on adult employment outcomes and children's academic outcomes (Ananat et al., 2011; Wolfe et al., 2012). Conversely, studies of the detrimental effects of lead (Lanphear et al., 2005; Reyes, 2012) may require an even finer geographic scale than the census block if exposure varies from building to building. These examples reflect a more flexible approach to the study of residential contexts in which the appropriate scale for the measurement of 'neighborhoods' is dependent on the specific theoretical mechanism under study (Galster, 2008).

Operationalizing individuals' exposure to the neighborhood represents an additional challenge. Although much of the empirical literature measures neighborhood conditions at a specific point in time or over a few years of an individual's life, empirical work on the rigidity of neighborhood inequality documents the stability of neighborhood conditions over the life course and across generations (Sharkey, 2008). A recent set of studies has found that the duration of exposure to the neighborhood environment is crucially important in understanding the effects of neighborhood disadvantage on educational attainment, cognitive development, and health (Pope et al., 2002; Sampson et al., 2008; Sharkey and Elwert, 2011; Wodtke et al., 2011).

The Next Stage of Research on Neighborhood Effects

Sharkey and Faber (2014) argue that much of the empirical literature on neighborhood effects has been dominated by the question of whether neighborhoods matter. The emphasis on this question has led to a narrow view of neighborhood effects, a view that is driven by the effort to standardize the measurement of neighborhoods and to confront selection bias in order to identify the causal effect of exposure to poor neighborhoods. Although the focus on methodological rigor has moved the field forward, we argue that the next stage of research on neighborhood effects should be driven by a more expansive view of the various ways in which the stratification of residential settings serves to maintain and reproduce inequality across multiple dimensions.

This approach to neighborhood effects places primary attention on the mechanisms by which residential stratification affects the spatial distribution of social, political, and economic phenomena as well as the life chances of different groups and populations. Neighborhood poverty is only one of many salient dimensions of a community, yet concentrated poverty and affluence have been the focus of much of the empirical literature. Research on the consequences of exposure to other dimensions of the immediate social and physical environment has received much less attention, despite the evidence that has been gathered on the effects of exposure to violence and the importance of air, noise, and soil pollution to child development (e.g., Ransom and Pope, 1992; Reyes, 2012; Sharkey, 2010). Research analyzing processes that operate in space frequently is overlooked in reviews of the neighborhood effects literature, yet is essential to understanding how phenomena such as poverty, illness, and violence come to be concentrated in certain communities and not others (Sampson et al., 2002).

The expanded availability of data on institutions, social and economic phenomena, the built environment, and the physical environment provides researchers with the capacity to generate evidence on a wider range of mechanisms for neighborhood effects (Downey and Van Willigen, 2005; Odgers et al., 2012; Pope et al., 2002; Schwartz, 2010; Sharkey et al., 2013; Small and Stark, 2005). Similarly, new forms of data on networks, use of space, and time use allow researchers to measure how individuals and groups use social space over time (e.g., see Almeida, 2005; Entwisle et al., 2007; Kwan, 2009; Papachristos et al., 2012; Wikström et al., 2012). These improvements in measurement have the potential to lead to a more refined view of the variation in individuals' exposure to different aspects of their residential settings and heterogeneity in individuals' vulnerability to the residential environment.

Methods for the study of neighborhood effects must continue to grapple with the challenge of selection bias, omitted variable bias, and the identification of causal effects. However, relying on exogenous variation in families' residential environments that arises through residential mobility programs is only one limited approach to these challenges. Several studies have exploited exogenous variation in the timing of specific events occurring in individuals' residential environments, such as local homicides or suicides (Hansen et al., 2013; Sharkey 2010), or shocks in local labor markets (Ananat et al., 2011; Lee et al., 2013; Wolfe et al., 2012), in order to identify the effects of changes in the residential environment on outcomes measured at the individual or community level. Another strand of research exploits place-based randomized controlled trials (e.g., Braga, 2005) or experimental audit studies (e.g., Besbris et al., 2014) to identify the effects of the neighborhood setting, or changes in that setting, on social and economic outcomes.

This research reflects a broader view of neighborhoods and neighborhood effects. To understand the role of neighborhoods it is important to move beyond the idea that concentrated poverty can stand in for every salient dimension of the residential setting, or that interviewing children after they have moved out of public housing is a sufficient way to determine whether neighborhoods matter. Our overarching argument is that researchers must take advantage of data on environmental conditions, social processes, institutions, and other dimensions of local context in order to uncover the many ways that residential settings affect the lives of individuals and reproduce patterns of social and economic inequality. In combination with new sources of data and more precise measurement, a set of innovative and rigorous analytic approaches is necessary to develop a more complete understanding of the role that neighborhoods play in the American stratification system.

Neighborhood Revitalization and Community Development

WD Keating, Cleveland State University, Cleveland, OH, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Neighborhood revitalization efforts and programs, both public and private, are reviewed. This includes early efforts at elimination of slums led by settlement houses, housing reformers, and social workers. This was followed by government programs like housing and health codes, public housing, urban renewal (both slum clearance and rehabilitation), model cities, neighborhood planning and redevelopment, and, most recently in the United States, the Empowerment Zone and Enterprise Communities program. The gentrification phenomenon is discussed. Various techniques of neighborhood revitalization are reviewed, as well as critiques of their impact. Likewise, community development programs, both public and private, are reviewed. Efforts undertaken in the United States by private foundations ('intermediaries') are reviewed as well. The role of community organizations like community development corporations are discussed. The impact of the mortgage foreclosure crisis on urban neighborhoods and responses to it are reviewed. Emphasis is primarily on the United States, with reference to North America and Western Europe.

Introduction

Neighborhood revitalization efforts and programs, both public and private, are reviewed. These include early efforts at elimination of slums led by settlement houses, housing reformers, and social workers. This was followed by government programs like housing and health codes, public housing, urban renewal (both slum clearance and rehabilitation), model cities, neighborhood planning and redevelopment, and, most recently, the Empowerment Zone and Enterprise Communities program. Various techniques of neighborhood revitalization are reviewed, as well as critiques of their impact. Likewise, community development programs, both public and private, and the role of community development corporations (CDCs) are reviewed. The primary emphasis is on the United States.

The Progressive Era: Tenement Reform and Settlement Houses

From the mid-nineteenth century through the beginning of World War I, the population of US cities swelled as a result of mass immigration, primarily from Europe. Most poor immigrants were concentrated in ethnic enclaves. In an era in which there were no governmental social and welfare services other than the poorhouse, poor immigrants lived in overcrowded and unsanitary housing and neighborhood conditions. In cities like New York, they lived in tenements in wretched conditions.

Around the turn of the century, the Progressive Era saw the rise of reform movements. These included the efforts of housing reformers to address the conditions prevalent in slum neighborhoods. New York City was in the forefront, led by a Tenement House Committee of reformers like Lawrence Veiller. The journalist Jacob Riis exposed slum conditions in his graphic descriptions and photographs of 'how the other half lives.' This led to the enactment of the New York Tenement House Law of 1901, designed to eliminate the worst abuses. It became a model for similar legislation in other states. However, reformers like Veiller were loath to invoke the government and were especially opposed to government-subsidized housing for the poor. Instead, they eventually turned to the adoption of municipal housing and health codes, setting minimum regulatory standards for residential housing (Friedman, 1968). A few philanthropists sponsored limited dividend model housing for workers but this failed to prove to be a viable alternative to the housing provided by private landlords (Birch and Gardner, 1981).

During the same period, a settlement house movement began, based upon similar previous efforts in England. Reformers supported by private philanthropy sought to alleviate social problems in slum neighborhoods. They established settlement houses to provide social services to the poor. Largely apolitical, they sought to uplift the poor, while trying to improve their living conditions. Leaders included Jane Addams in Chicago and Robert Woods in Boston (Fisher, 1984; Halpern, 1995).

Slum Clearance: Public Housing

It was not until the Great Depression of the 1930s that public housing appeared in the United States, decades after its adoption in Europe. The Depression exacerbated already existing problems in poor urban neighborhoods. The reforms of the Progressive Era had done little to alleviate the underlying causes of the slums and substandard housing. A new generation of activist housing reformers argued for intervention of the federal government to replace slum housing with government-financed, -owned, and -operated public housing. This was a radical departure from US policy.

Reluctantly, the New Deal administration of President Franklin D. Roosevelt began a program of building public housing as part of a public works slum clearance program aimed at providing work to unemployed workers in the building trades. The real estate industry fought hard against the creation of public housing, arguing instead that private landlords should provide for the housing needs of low-income persons. The 1937 legislation provided federal financial assistance to those local governments that chose to participate

 http://dx.doi.org/10.1016/B978-0-08-097086-8.74018-9

in a program to provide decent, affordable housing for the poor. Local public housing authorities were to construct and operate the public housing projects. The real estate lobby was successful in limiting public housing to the poor and imposing limits on the amounts allowed for public housing units. In addition, public housing could only be built to replace substandard units. These limitations would later prove fateful in undermining the goals of the reformers and dooming the expansion of public housing. Despite the attempts of a few localities, racial segregation of public housing prevailed, reflecting racist attitudes and existing housing and neighborhood patterns.

The public housing program began slowly was interrupted by the emergency of World War II and barely survived conservative opposition in the housing act of 1949. It was adopted primarily by large cities with a preponderance of the poor, which received most of the funding and engaged in the construction of large-scale public housing projects. Even with its limitations, public housing was a great improvement over the slum housing that it replaced. In its early stages, public housing served as housing for the working poor.

However, as the public housing grew older, its population in the 1960s became poorer (Meehan, 1979). The housing projects were often physically isolated, in poor condition, and racially segregated – despite increased federal subsidies and court mandates. Except for housing for the elderly poor, new construction of public housing virtually ended in the 1970s. Instead, the US government switched to providing subsidies to enable poor tenants to rent private rental units. Beginning in the 1990s, some of the most notoriously unsuccessful public housing projects were either demolished or reduced in scale and rebuilt as mixed-income housing through the HOPE VI program. Through its fiscal year 2010, the US Department of Housing and Urban Development (HUD) reported that 96 017 'distressed' public housing units had been demolished and 83 951 replacement units were built, of which 82 425 had been occupied. Affordable housing advocates expressed concern about the loss of low-rent units and the lack of decent, affordable relocation housing for those displaced (Popkin et al., 2004; Bennett et al., 2006; Goetz, 2010, 2011a,b). Critics have also termed the impact of HOPE VI as a form of gentrification (Goetz, 2011a,b). For those displaced public housing tenants who did not return after the sites were redeveloped, a majority were relocated in other public housing projects. Most of the rest received vouchers and mostly moved to nearby neighborhoods. They found these to be better in some respects (e.g., safety) but more expensive. Loss of social ties offset relocation to these neighborhoods, which were generally racially segregated (as were their former public housing projects) (Fraser et al., 2012).

After the administration of President George W. Bush failed to terminate the HOPE VI program, its successor phased it out in favor of a Choice Neighborhoods program. Intended to broaden the impact to 'distressed' urban neighborhoods by linking improved housing to schools, public transit, and employment opportunities, planning grants were awarded in 2011 to 13 communities.

Despite the bad reputation of several projects nationally, for the most part public housing in urban areas did contribute to the elimination of the worst slum conditions.

Slum Clearance: Urban Renewal

Planning for postwar redevelopment in US cities began in the early 1940s. Liberals favored large-scale slum clearance, replacing them largely with public housing (Gelfand, 1975). In 1949, Congress approved an urban redevelopment program, which would eliminate slums and 'blight.' However, as it unfolded, prime downtown real estate became the focus of urban renewal in many cities. Instead of public housing, this land was reused for commercial and industrial facilities, luxury housing, and institutional uses. Despite assurances of relocation and replacement housing, hundreds of thousands of poor slum dwellers saw their neighborhoods and housing destroyed but their housing conditions worsened instead of improving as little new low-rent public housing was constructed on urban redevelopment sites (Greer, 1965). New York City under the leadership of Robert Moses provided some of the most egregious examples of this process, although Moses also built many of the best public housing projects in the United States (Caro, 1974).

The program was renamed as 'urban renewal' in 1954. The newly elected Republican administration of President Dwight Eisenhower, while not opposed to urban renewal, was concerned about its cost to the federal government and the possibility that much of the cleared land was not proving to be attractive to private, for-profit developers. It tried to change the focus of urban renewal in part to conservation and rehabilitation, which it saw as less expensive. Urban renewal clearance and redevelopment policies would later be condemned as bad planning by critic Jacobs (1961) in a famous critique.

In the 1930s, the realtors opposed federal intervention in the housing market and proposed neighborhood associations as the primary vehicle for neighborhood conservation. This was aimed primarily at homeowners' associations. This often had an exclusionary aim, with white homeowners organizing to prevent any entry by African Americans and other minorities. This is also the era in which the newly created Federal Housing Administration (FHA) adopted the racist standards of the real estate industry to rate neighborhoods for the purpose of making and insuring home mortgage loans. This became the basis for the 'redlining' of older urban neighborhoods and contributed to the exodus from these neighborhoods to the suburbs after World War II.

Many urban neighborhoods, mostly poor, also were destroyed to make way for central city links to the interstate highway system created in 1956. As with urban renewal, promises of decent, affordable replacement housing often went unfulfilled. Not all neighborhoods designated as slums for urban renewal or highway construction were necessarily blighted (Gans, 1962). Where residents did organize to oppose the demolition of their neighborhood, typically they failed because they did not have political influence and had no legal standing in court to challenge these plans.

This finally changed in the late 1960s, following summers of riots in US cities from 1965 through 1968. Citizen participation finally was mandated and neighborhood residents at least had an opportunity to present their views. Advocacy planning arose to provide neighborhood residents with the capacity to develop alternate plans. The courts finally recognized the right of those to be displaced to challenge plans,

typically on the ground that there was insufficient replacement housing available to meet federal requirements (Hartman, 1974). Community resistance led to the demise of large-scale clearance for urban renewal and highways in the central cities by the early 1970s (Klemek, 2011).

Model Cities

It was felt that displacement of poor and minority residents for these purposes contributed to the resentment that sparked so many of the urban riots of the 1960s. Resident participation in planning led to more serious consideration of rehabilitation of blighted neighborhoods rather than clearance and redevelopment. The first major example of this policy shift was embodied in the Model Cities program launched by a newly created HUD in 1967. In contrast to urban renewal slum clearance, this reaction to the urban riots proposed to concentrate federal, state, and local resources to improve targeted poor neighborhoods. Housing rehabilitation, social services, job training, and community participation were hallmarks of this approach. Due to insufficient funds, intergovernmental coordination problems, and a change from the Johnson to Nixon administration after the 1968 presidential election, Model Cities failed to fulfill its promises (Haar, 1975).

Community Development Block Grants

In 1974, the urban renewal and Model Cities programs, among others, were ended and replaced by the Community Development Block Grant (CDBG) program. The CDBG program was intended to give local governments more discretionary control over spending and to involve more communities (Hays, 1995). However, CDBG funds were supposed to benefit primarily low- and moderate-income residents. This caused controversy in many localities and often led to wider dispersal of funds, to the detriment of those neighborhoods most in need of assistance (Rich, 1993). This era marks a shift in federal policy that persisted through the Clinton administration, emphasizing devolution of responsibility for many federal aid programs and resulting in cutbacks in many HUD housing assistance programs.

Federal Recognition of Neighborhoods

Federal policy since the 1930s did not usually recognize neighborhoods. HUD and its predecessor agencies made grants and loans to cities and states, and developers and lenders, and provided insurance to individuals (homebuyers). In 1977, President Jimmy Carter made the unprecedented move of appointing an Assistant HUD Secretary for Neighborhoods and created a small program that for the first time awarded grants directly to neighborhood development organizations (Mayer, 1984). In 1979, Carter appointed a presidential commission to advise him on neighborhood policies and programs but then disregarded its recommendations. His successor President Ronald Reagan immediately dismantled Carter's modest neighborhood initiatives at HUD.

Redlining and Community Reinvestment

One of the major reasons for the decline of older urban neighborhoods was their 'redlining.' Lenders, insurers, and realtors avoided those neighborhoods that had a significant minority population on the basis that their presence jeopardized real estate values and would cause white flight. Federal agencies, most notably the FHA, followed suit. This in turn almost assured that eventually these neighborhoods would become all or predominantly minority occupied. 'White flight,' triggered by unscrupulous real estate practices, then occurred in many neighborhoods (Jackson, 1985).

Chicago, where such segregationist practices as 'racial covenants' originated and long the most racially segregated city and metropolitan area in the United States, was the focus of organizing in the 1970s against lender disinvestment in urban neighborhoods. Neighborhood organizers demanded that lenders cease redlining and invest in neighborhoods. Racial discrimination in housing and lending had been previously outlawed, although enforcement of this legislation has yet to end such practices. The antiredlining movement spread and eventually led to the enactment of federal legislation in 1975 and 1977 requiring federally regulated lenders first to disclose generally where their loans were made and then to serve all the communities within their territory. The US Congress rejected more restrictive proposals. The movement then used this Community Reinvestment Act (CRA) legislation to document lender discrimination against older neighborhoods and to require lender commitments to again lend in these neighborhoods. This has led to major lender commitments in many cities (Squires, 1992; Schwartz, 1998). This is a critical component of neighborhood revitalization, especially when the federal government was reducing its role in aiding urban areas. During the mortgage foreclosure crisis, some conservatives attempted to blame the CRA for the high rate of foreclosures in poorer neighborhoods, a claim which has been refuted (Immergluck, 2009).

Gentrification of Urban Neighborhoods

Beginning in the late 1970s, a contrasting phenomenon to disinvestment began. In many large cities, middle- and upper income newcomers began to discover and move into older neighborhoods in decline near downtowns (Palen and London, 1984). These 'urban pioneers' renovated buildings that were typically in disrepair. As their numbers increased, these neighborhoods saw other changes, particularly in the quality of services, both private and public, reflecting the demands of the affluent newcomers.

City governments viewed this process as benign, with improvements in the physical quality of neighborhoods and increased tax revenue. However, in many of these neighborhoods, lower income residents were displaced, directly or indirectly, because they were relocated for building renovation or could not afford rehabilitated housing. There was also often a clash of lifestyles between the residents and the newcomers. While the magnitude of gentrification-based displacement was debated (Schill and Nathan, 1983), many localities did institute land use and housing regulations to provide some

protection to residents against displacement and to ensure the replacement of lower priced housing units (Keating and Smith, 1996). The debate over the impact of gentrification has continued (Brown-Saracino, 2010).

The Emergence of Community Development Corporations

In the 1960s, the US Congress funded directly the CDCs. They are nonprofit community-based organizations operating in distressed, mostly urban and central city neighborhoods. Many originally derived from community organizing. Many are church sponsored. They attempt to address both social and physical problems. They have expanded greatly in number, totaling several thousands by the 1990s (Vidal, 1992). In larger cities, there are now citywide networks of CDCs.

CDCs engage in a variety of activities, typically housing and commercial development, job training, and, to a lesser degree, social services (Erickson, 2009). They are funded from a wide variety of sources, including all levels of government, philanthropic foundations, and corporations (Vidal, 1992). The impact of CDC activities has been rated positively (e.g., Rohe, 1998; Walker, 1993). Nevertheless, they continue to face organizational and financial challenges (Bratt and Rohe, 2004).

However, it must be conceded that, despite the often heroic efforts of CDCs and companion social service agencies, measurable levels of distress such as poverty and crime have increased rather than decreased in many urban neighborhoods since the advent of CDCs (Rusk, 1999). CDCs are simply not enabled or funded to deal with the entire myriad of social and physical problems in distressed urban neighborhoods. Ultimately, governments in partnership with nonprofit organizations, residents, and so-called intermediary funders are responsible for the revitalization of neighborhoods.

Neighborhood Revitalization Techniques

A variety of techniques have been used in the revitalization of neighborhoods. Resident attitudes toward their neighborhood have been surveyed (e.g., Ahlbrandt and Cunningham, 1979). Neighborhoods have been classified according to their physical and social characteristics (Keating and Smith, 1996). Public programs have often targeted neighborhoods, based upon their profile and degree of need for assistance. Housing has been newly constructed and rehabilitated for both lower and moderate-to-middle-income range occupants (Rohe et al., 1998; Walker, 1993). The low-income housing tax credit, which enables private corporations to profitably invest, is a critical factor in the provision of much affordable housing. In badly deteriorated neighborhoods, an urban homesteading approach has been tried to encourage self-help rehabilitation (Varady, 1986). Existing and new businesses have been subsidized to improve their buildings, expand their operations, and assist in the training and employment of neighborhood residents. Neighborhood plans have been developed, with and without resident participation, to identify serious problems and programs and policies to alleviate them (Rohe and Gates, 1985). A favored technique is the mapping of neighborhood assets as cornerstones for neighborhood revitalization. Neighborhood organizing remains a key ingredient in successful neighborhood redevelopment, with block clubs often being the cornerstone of neighborhood organizations (Medoff and Sklar, 1994). Neighborhood organizing can be confrontational or cooperative, depending upon the circumstances and the style of organizing (Fisher, 1984).

The People versus Place Policy Debate

A major debate in neighborhood revitalization has been termed people versus place. In 1968, the US national commission on urban riots posed the dilemma of whether to rebuild poor ghetto areas or try to disperse and integrate their mostly minority residents into mainstream society. More than four decades later, this debate continues (Goetz and Chapple, 2010). Downs (1994) has posed alternate strategies aimed at either improving the social fabric and economic and physical conditions of impoverished inner city neighborhoods or providing mobility in work and housing to enable their residents to move to better neighborhoods in central cities and the surrounding suburbs. As previously discussed, the HOPE VI program was intended to replace demolished distressed high-rise public housing projects with mixed income, low-rise housing that would improve the lives of the low-income tenants. There have been a few small-scale housing mobility experiments to disperse the poor, first in Chicago related to the desegregation of public housing and then as a demonstration program (Moving to Opportunity) in five cities (Polikoff, 2006; de Souza et al., 2010). However, this has not become a national policy. [M]ore emphasis has been placed on the revitalization of inner city neighborhoods with the goal of their improvement for the existing residents.

The latest example in the United States of the latter approach is embodied in the Empowerment Zone and Enterprise Community program that was launched in 1994. It was a belated response to the 1992 civil disturbance in south central Los Angeles. Using a combination of employer tax credits, subsidized loans for businesses, and special funding for social services, including job training, the aim was to provide employment primarily in designated high-poverty areas in more than 100 communities (Gale, 1996). The results from this short-lived program were only mixed at best (Rich and Stoker, 2010).

The Impact of the Mortgage Foreclosure Crisis on Neighborhoods and Responses

In addition to existing problems like substandard housing, many poor urban neighborhoods began to experience a new problem in the early part of the twenty-first century in the midst of a housing bubble: 'predatory lending.' Ironically, in the past, many of the same neighborhoods had been 'redlined' by lenders who refused to lend, claiming unacceptable borrower risk. Their residents were now targeted by mortgage brokers offering mortgage loans, including refinancing, to those

otherwise previously deemed either only marginally eligible or ineligible due to low incomes or poor credit ratings. These 'subprime' loans, often financed indirectly by major lenders, contained high interest rates and terms unfavorable to borrowers, who often did not understand these loan terms. In the most egregious cases, borrower incomes were exaggerated, down payments were arranged by brokers, and only low or no down payments were required. Worse, so-called liar loans contained false information regarding borrower income or employment.

As a result of these predatory loans, many of the borrowers defaulted, leading to growing foreclosure rates. As the lenders foreclosed and the homeowners departed, these vacant homes became targets for those who stripped them of any valuable amenities. In a recessionary economy and a housing crash, lenders found that buyers became scarce. State foreclosure laws sometimes contributed to the time that these vacant homes became vulnerable to vandalism. As economic problems escalated, many homeowners with regular, 'prime rate' mortgages were also unable to meet their obligations and lost their homes to foreclosure. Increasingly, millions of US homeowners found themselves 'under water,' i.e., the plummeting value of their homes was worth less than the amount ('principal') owed to the mortgage lender, leading many to simply walk away and abandon their home. Cities found themselves spending much more to maintain vacant homes abandoned by these owners, and not being maintained by foreclosing lenders. The entry of so-called bottom feeding speculators purchasing these homes at auction or in bulk from lenders and then 'flipping' them, i.e., reselling them quickly after cosmetic repairs, further exacerbated the situation.

The responses of the federal government beginning in 2008 have failed to save millions of homeowners from foreclosure. This has included a program to counsel homeowners in order to prevent foreclosure by persuading lenders to modify mortgages to make them more affordable. The federal government also placed the two bankrupt government-sponsored enterprises into conservatorship and has had to bail them out at huge cost to the taxpayer. They now own and finance most of the residential mortgages in the United States. The so-called robo-signing scandal led to a 2012 agreement between the state attorneys general and five major lenders to make changes in mortgage modification processing and provide some modest restitution to victims of predatory lending.

To help localities to demolish abandoned nuisance properties, assist homeowners, and build affordable housing in targeted neighborhoods, the federal government created a Neighborhood Stabilization Program. While three rounds of funding assisted many localities, the amount of funding fell far short of the need (Mallach, 2009). Therefore, without additional federal aid, until the housing market revives, localities face the prospect of a continuation of the cycle of foreclosures, abandonment, demolitions, and a large number of blighted properties plaguing many of their neighborhoods. However, in many of these communities, local governments and community organizations have created land banks to address abandoned housing and initiated the reuse of vacant land (e.g., urban agriculture) in neighborhoods hit hard by foreclosures (Mallach, 2010).

Neighborhood Revitalization in Canada and Western Europe

Urban revitalization and regeneration programs in Canada and Western Europe are similar to approaches in the United States described above. However, the context is much different. Governmental systems typically feature national and regional policies, programs, and agencies. Municipal authorities may have less authority than in the United States. With few exceptions, the levels of poverty and distress do not compare with the United States, with the exception of industrial cities in sharp decline. Finally, there has not been nearly as much racial conflict in the cities of Canada and Western Europe as in the United States, again with some exceptions, and backlash against immigrants in some countries. The urban regeneration programs of the United Kingdom have been similar in many respects to those in the United States (Jones and Evan, 2008; Lawless, 2010). Urban regeneration programs in Europe vary widely but with an emphasis on sustainability and addressing social exclusion affecting poorer populations (Colantonio and Dixon, 2011; Couch et al., 2003). Beginning in 1994, the European Union launched an URBAN Community Initiative, aimed at the regeneration of deprived neighborhoods. The Regenera network, financed by the European Urbact program, focuses on physical urban renewal; integration of ethnic minorities, accessibility, and transport; and the organization of local communities in 13 cities in 8 European countries (Regenera, 2007).

For an earlier comparative perspective on urban regeneration in North America and Europe, see Judd and Parkinson (1990). For an earlier comparative perspective on neighborhood revitalization in Australia, Canada, and Western Europe, see Gale (1984). More recently, some Western European countries also experienced a housing bubble and then a crash, leaving an escalating number of homeowners facing foreclosure and vacant houses unsalable in a depressed housing market, most notably in Ireland and Spain. Recent higher levels of unemployment resulting from an economic recession have added to the problems of poorer urban areas.

Neocolonialism and Social Work

Vasilios Ioakimidis, Durham University, Durham, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Arguments about the colonial and imperialist character of international social work initially emerged in the 1970s as part of the broader postcolonial movement in social sciences. Since then these approaches have remained on the sidelines of mainstream social work literature. However, the recent reinvigoration of the indigenization debate has provided an important context for social work to reexamine its political character and scope as a 'global profession.' This article critically evaluates the evolution of the postcolonial debates in social work. The author argues that the process of social work 'decolonization' requires broad alliances with the oppressed populations on the basis of challenging neoliberal capitalism.

Introduction

Postcolonialism refers to a set of theoretical concepts, approaches, and interventions, which deal with the diverse effects of the interaction between the colonizer and the colonized. The conceptualization and focus of the postcolonial analyses is very diverse and informed by different schools of thought. Postmodern and Marxian approaches have significantly influenced the formation of the most important postcolonial discourses. These origins provide a distinct critical edge in the postcolonial analysis and often encourage specific actions toward the multilevel liberation and emancipation of communities, which have suffered from isolation, oppression, and discrimination as a result of colonialism. The vast differences between postmodernism and Marxism create a diverse, rigorously debated and inherently self-contradictory postcolonial analysis. Even within the broad realm of critical theory, certain aspects of postcolonialism are targeted by objections and criticisms. The lack of an – even loosely – homogenous discourse and the fragmentation of oppressed peoples' experiences in the name of an ill-defined diversity, have created space for a heated debate within the communities of theorists, scholars, activists, and social movements (Barlow, 1993; Madsen, 1999).

Despite this diversity in origin and knowledge base, one could broadly identify the major domains of discourse that are of interest for postcolonialism as follows:

1. *The historical context of colonialism.* Postcolonial analyses identify the beginning of 'colonialism' in the period of rapid and violent colonial expansion of European powers. The need for natural resources, quest for global control, and competition between European empires introduced a new epoch of exploration, expansion, and exploitation. Such expansion not only involved military might and physical violence but also the forceful conversion of local 'indigenous' populations into the cultural, philosophical, political, and religious principles of the colonial powers. Slavery, racism, and orientalism are creations of this period (see Hobsbawm, 1975). The industrial revolution did not end colonialism, but merely changed its form and practices. Liberation movements and the eventual independence of colonies in the twentieth century generated an intense debate attempting to identify and analyze new forms of colonialism.
2. *The impact of colonial domination on (primarily) colonized populations and the effect of this process on the diverse population of the colonial powers.* Along with the evident and well-documented explicit policies/practices of inhumane treatment and exploitation of the colonized peoples, indirect methods of subordination are often absent or neglected from academic discussions. These methods include the suppression of local cultures, extinction of languages, and degradation of local knowledge and value systems. The main reasons behind the lack of analysis on these practices is linked to a history of aggressive, sophisticated, and persistent colonial assimilation, making oppressed communities weak in resisting such powerful domination. 'Divide and rule' has been a particularly popular strategy among colonial powers (Callinicos, 2009). Consequently, oppressed peoples have internalized oppression and consider the colonial and postcolonial domination as a 'natural order' (Freire, 1970).
3. *The creation of a theory and praxis deconstructs 'given realities' and attempts to emancipate oppressed peoples.* Postcolonial approaches have provided an important tool in analyzing or reconstructing power relations and multiple layers of colonial domination. Such analysis has informed and encouraged a number of social movements aiming at the emancipation and self determination of oppressed groups. Indigenous and antiracist movements have been particularly influenced by postcolonialism.

The term 'postcolonialism' in the literature highlights the historical realities and sociopolitical challenges, which emerge in parts of the world *after* (post) the end of the colonial era. According to this approach, postcolonialism deals with complex issues related, inter alia, to identity, culture, ethnicity, language, and democracy, in countries which had experienced the colonial domination. This claim is fundamentally opposed by leading postcolonial theorists, postcolonialism as it significantly reduces the scope, historical significance, and complex power relations characterizing the interaction between colonial countries and colonized societies (see Ashcroft et al., 1995). The latter approach favors a holistic over a chronological or culture-specific one. In this respect, postcolonial issues do not emerge *after* the conclusion of the colonial. Postcolonial issues, defined by these power relations, arise instantly at the point of interaction between the colonial power and colonized

 http://dx.doi.org/10.1016/B978-0-08-097086-8.28061-6

populations and happen simultaneously at both ends. Fundamental aspects of such dialectic interaction exist and persist even after the 'conclusion' of the colonial era. As Ashcroft et al. (1995: p. 117) explain

> Post colonialism … does not mean post-independence, or after colonialism, for this would be to falsely ascribe an end to the colonial process. Post-colonialism, rather begins from the very first moment of colonial contact. It is the discourse of oppositionality which colonialism brings into being. In this sense, post-colonial writing has a very long history.

In this excerpt, Ashcroft et al. skillfully identify some of the major antinomies within debates on defining postcolonialism. The first, which I already addressed, deals with the boundaries of postcolonial discourse with regards to the binary interaction between *time* and *space* (i.e., *when* and *where* do 'postcolonial affairs' occur?).

The second theoretical constraint identified by Aschroft et al. is of intellectual eclecticism. As I suggest later, postmodernism, mistakenly considered the only source of epistemological analysis within postcolonialism, has produced some theoretically inconsistent discourses. Some of the most important postcolonial scholars have developed rigorous and robust critiques on the inadequacies of postmodern approaches. Moreover, postcolonial analysis precedes the postmodern one, and thus – both ideologically and epistemologically – distinctions need to be highlighted.

Debates about the representation of oppressed populations and the (in)ability of postcolonialism to give voice to these groups provide interesting examples of the aforementioned tensions. Gayatri Spivak, a celebrated scholar in postcolonial studies, has epitomized the ongoing soul searching within postcolonialism asking the vital question 'Can the subaltern speak?' In her homonymous book, Spivak (1988) explains that any person or group who has become educated through the dominant/mainstream institutions and is able to communicate ideas through conventional 'Westernized' channels of communication cannot claim that they are in a position to represent the oppressed 'native' population. Inspired by Gramscian analysis, she utilized the term 'subaltern' to describe exactly this population of indigenous peoples who live and operate beyond the sphere of Westernized systems and institutions. The question, "who qualifies to give voice to the 'subaltern'?" highlights fundamental political and ethical issues for social workers who often keep for themselves the roles of representation and advocacy. Spivak's critique demonstrates the potential fallacy of postcolonialism according to which the West could use its premises, language, value systems, and research tools while speaking *on behalf of* the 'subaltern.'

Part of the problem of representation is linked to the imaginary, 'mythical,' and biased Western views on understanding and describing the *other*. Edward Said's work on this domain has been of unparalleled importance. In his seminal work *Orientalism*, Said (1978) produces a discourse analysis of the Western impressions of the 'Orient.' He focuses on the nineteenth and twentieth centuries and mostly refers to the Arabic populations of the Middle East. Said's (1978) work eloquently demonstrates how the romanticized and prejudiced Western ideas of the 'Orient' have been historically part of the broader imperial agenda. In this sense, art, culture, literature, and aesthetics can play a major role in carving a certain image about oppressed populations and eventually justifying certain geopolitical interventions based on such prejudices. According to Said (2008: p. 8), "orientalism is never far (…) from a collective notion identifying 'us' Europeans against all those 'non-Europeans' and indeed it can be argued that the major component in European culture is precisely what made that culture hegemonic both in and outside Europe: the idea that European identity is a superior one in comparison with all the non-European peoples and cultures."

A Brief Reflection on the Colonial and Imperial History of Social Work

Within social work literature and practice, there is a noteworthy contradiction. Even though social work in many parts of the world has been a well-calculated product of colonial and imperial conditions, only a fraction of mainstream debates, literature, and practices has dealt with these serious issues. Questions about the imperialist nature of social work, emerged relatively early in the history of international social work, but never gained prominence. Postcolonial and antiimperialist analyses have existed in the margins of social work literature (see Dominelli, 2012; Midgley, 1981). A recent reemergence of these debates has been driven by mainstream postmodern analyses on culture and identity issues and largely focuses on the indigenization agenda. As we discuss below, this debate is rather narrow in scope and predominantly focuses on First Nations in Canada, Aboriginals in Australia, Maori in New Zealand, and Native Americans in North America, excluding – at least in Anglo-American literature – a very diverse history of indigenous movements in other parts of the world, which has engaged with broader alliances, class struggles, and radical theories. There are, of course, some notable exceptions to this rule such as Dominelli (2012), Ferguson et al. (2004), Lavalette and Ioakimidis (2011).

Much of social work history is inextricably linked to the emergence and perpetuation of the broader politics of colonialism and imperialism. The process of international social work development emerged in two main chronological waves. During the 1930s and early 1940s social work was imported to countries experiencing the British colonial rule. People in India, Cyprus, and the West Indies witnessed the emergence of a 'new' and rather 'alien' profession, which focused its marginal work on poor families and 'antisocial behavior' of children and young people. The development of social work at the time seemed peripheral and it was detached from any notion of adequate welfare state similar to that debated and eventually developed in the UK. In a climate of broader political repression, colonial social work was largely influenced by the toughest Victorian principles of social order and moralism (Ioakimidis, 2011; Midgley, 1981), with the forms of social work introduced at that time, a caricature of the metropolitan British system. The lack of a welfare system – even in an embryonic stage – the absence of democratic institutions and the violence of colonial rule allowed little space for the

development of a social work relevant to local needs. In Cyprus, for example, only the most punitive and prescriptive dimensions of British social work and youth probation systems were imported from the UK (see Triseliotis, 1977). Other, more inclusive and universal forms of welfare provision never made it to this island.

The second wave of international social work development emerged in the immediate aftermath of World War II. The creation of a global 'bipolar' power system and the subsequent tension between the main superpowers initiated a long period of antagonism known as the 'Cold War.' The United States of America immediately introduced a double-edged foreign policy aiming at tightening control over its proclaimed spheres of influence while actively suppressing the 'threat' of communism at a global level. In pursuing this aggressive policy, the US not only utilized its overwhelming military might, but also promoted economic, cultural, and social domination (see Hoogvelt, 2007). The need for postwar reconstruction in Europe and other parts of the world seemed to be a unique opportunity for the USA to extend its imperial control and win 'hearts and minds' of the people within its sphere of influence. The gigantic Marshal Plan in Europe and the manifold operation of United Nations Relief and Rehabilitation Administration and United States Agency for International Development in the Middle East, Africa, and Asia provide characteristic examples of imperialism through 'humanitarian assistance.'

Social work at the time seemed a very important tool in expanding and promoting this agenda. American social workers were sent to countries of US interest as part of missions that – not infrequently – included military personnel and policy technocrats. Greece and Turkey were the first countries to witness such top-down social work development as part of the postwar imperial project. In fact, in Greece, social work emerged in the middle of a vicious Civil War between the US backed National army and the socialist Democratic army. As Ioakimidis (2011: p. 516) indicates

> the main paradox of social work is that at times it can be both humane and also lacking in compassion or a sense of humanity. In the Greek case, international social work had no reservations in working closely with an authoritarian regime. The idea that social work can be used as a sophisticated and professionally advanced method of making the dominant socio-economical system operate more efficiently has long informed the development of international social work.

Korea, Vietnam, Italy, and Latin America provide similar examples of countries or regions where social work development was wedded to the specific agenda of US imperialism.

The Social Work Indigenization Question

An inevitable outcome of the aforementioned political dynamics was the creation of a colonial social work, which was, at best, irrelevant to local populations and, at worst, was explicitly oppressive and often racist. Shaped by these colonial interests, social work had to engage with extremely oppressive institutions and regimes; notwithstanding its much celebrated commitment to human rights. Racist incarceration and segregation systems (South Africa), harsh and politically motivated child care and adoption policies (UK–Australia), collaborations with dictatorial regimes (Greece, Chile, Argentina) are only few examples of the unpalatable dark and colonial side of social work history.

As national liberation movements and the movement of 'Third Worldism' (see Worsley, 1967), gained momentum in international politics in the early 1970s, anticolonial approaches became increasingly influential in social sciences. A major strand within this realm was the indigenization movement (Atal, 1981), which despite its original dynamism, by the beginning of 1980 had lost its momentum. Within social work, however, indigenization retained some impetus and during the past three decades and reemerged as a central theme in the late 1990s.

One of the reasons, behind the interest in social work indigenization is the very nature of the profession in the developing world and its use as a tool for humanitarian and political intervention. Despite the generous international funding that accompanied the creation of social work in much of the developing world as well as the constant 'scholar support' from Anglo-American academics, local welfare officers immediately recognized the tensions, contrasts, and ultimately the unfeasibility of the new profession. In order for social work to be established and successful in the long term its content and scope had to be relevant to the local context and needs. Antiintellectualism, limited academic debate, marginal job opportunities, and professional unrecognizability are only persistent symptoms of the artificial, alien, and 'top-down' construction of social work in these regions.

Within this context, it does not come as a surprise that one of the first recorded discussions of social indigenization was written by a United Nations regional welfare officer operating in Africa. In this early analysis, Shawky (1972) identified the failures in transferability of social work expertise. Unless 'adapted to fit local needs,' social work could be of little benefit for the overall process of modernization in the developing world. Therefore, he suggested that the United Nations as well as the newly developed social work profession should ensure that the imported technical knowledge is tailored in a meaningful fashion for the indigenous populations. Four years later, Resnick (1976: p. 22), adopting a rather similar approach, described indigenization as "(the) process of relating social work function and education to the cultural, economic, political and social realities of a particular country."

It was not until 1981 that the first detailed and well-documented critique of the colonial, and thus potentially oppressive, nature of international social work emerged. Midgley's (1981) seminal work on the reality of professional imperialism embedded in much of international social work activities still remains a key text in understanding the antinomies of international social work. In this book, Midgley (1981) scrutinized the – rather limited at the time – international social work literature and utilized empirical data from personal communications with social workers in Africa. Midgley, demonstrated the inadequacy and irrelevance of social work curricula in the developing world. Most importantly, he moved beyond the descriptiveness and

antiintellectualism of mainstream international social work literature attempting to demonstrate the importance of the sociopolitical context within which social work operates. His most important achievement and contribution to social work scholarship was the ability to highlight the clear connections between international social work and the broader geopolitical context.

At roughly the same time, a much more politicized discourse emerged in Latin America. Latin American academics and students, influenced by the success of regional revolutionary movements, adopted a Marxist-socialist critique on the nature and character of social work. At the core of this critique was the interconnection between geopolitical imperialism and the international social work project. In this sense, Latin American academics broadened their analysis, dismissing much of the previous 'indigenization' discussions as developmentalist and abstract. According to their analysis, what the social work needed was not only a departure from its imperialist past but the creation of a new '*authentic*' Latin American theory and practice; one that meets the local needs of oppressed classes and promotes the idea of revolutionary change in society. Wolfe (1972) tried to capture this dynamic debate within Latin American social work explaining that

> There is apparent, a generalized and serious attempt on the part of university schools and professional associations to develop social work theories with authentic Latin American orientation and meaning, and to discover from their practice, which is rich but never as yet documented nor analyzed nor conceptualized, techniques more applicable to the problems under the unique situations of the countries of the region.
>
> Wolfe, 1972: p. 33

The idea of 'authentization' dynamically reappeared in social work literature the in late 1980s by Walton and Abo El Nasr. In their analysis of Egypt, the authors (1988) included some of the elements of the Latin American argument for liberation from both the orthodoxies of international social work and the triviality of the indigenization debate. Moreover, they suggested that there was a further need for 'authentization' of social work, which goes beyond simply 'modifying' and adapting Anglo-American social work. Walton and Abo El Nasr argued that

> The pattern of social work is modified by the nature and circumstances of Egyptian society. Also we have to search or look for the authentic roots in the local system to create or build a domestic model for social work in the light of the needs, problems and circumstances prevailing in Egypt (1988:143).

While highlighting the need of searching and documenting social work practices that are relevant to local cultural needs, Walton and Abo El Nasr, distanced themselves from the Latin American paradigm of politicized social work. Their analysis adopted developmentalist approaches, which failed to address the big political questions of inequality at a domestic level and imperialism at an international level, and despite its originality and importance, implied a rather apolitical social work process.

Nevertheless, Walton and Abo El Nasr's references to the importance of local culture were to be further appreciated and explored toward the end of the twenty-first century. A rise in academic interest on the contested theme of First Nations, along with the rapid expansion of social work in China, renewed the discussion about the nature of international social work theory, practice, and educational exchanges (see Yunong and Xiong, 2008). This was a particularly fertile soil for the growth of postmodern analyses in the field of social work.

The nature, epistemology, and scope of postmodern approaches suggested that the debate on social work should drift away from the, vaguely defined, politics of 'modernity' and focus on culture, identity, and diversity. 'Eurocentrism' along with the 'grand narratives' of Modernity (an equally obscure and problematic jargon) were deemed irrelevant to the experiences of the 'local populations.' Decolonizing social work meant that social work had to adopt a strategy for 'the liberation project of Indigenous Peoples and a call to liberate social work from its modernist shackles' (Briskman, 2008: 83). However, as we will see below, this call was rather confusing and abstract as it neither specified the 'constraints of modernity' nor acknowledged the structural inequalities within 'indigenous societies.' Interestingly, part of the criticism against the indigenization of social work came from China. Yunong and Xiong (2008) in a well-argued response against mainstream postmodern approaches highlighted that proponents of the indigenization agenda blindly adhere to existing indigenous structures, ignoring whether such structures advance the betterment of the people or not. Moreover, they suggest that in a rapidly globalized world a fixation with locality is rather monolithic and unable to grasp the dynamism and complexities of the interconnected global and local political debates.

As epistemological, ideological, and theoretical tensions on the issue of indigenization rise, the social work field can only benefit from this rigorous examination of some of the most persistent and inherent contradictions of the profession.

Rethinking 'Indigenization': Toward an International Social Work of Liberation

Discussions on the oppressive nature of 'top-down' Anglo-American social work practice in the 'developing world' are very important in highlighting the need for alternative theories and practices. However, as I also explained in this article, the narrowness of the social work indigenization debate has not allowed for the exploration of concrete theoretical alternatives, which can address the fundamental and structural inequalities caused by neoliberal capitalism and imperialism.

Part of this problem, is linked to the distinctive theoretical relativism and obscure language, which is so characteristic of postmodern analyses. Claiming that social work should be liberated from the restrictions of modernity and challenge all 'fundamental truths of Modernity' might sound as a call for resistance but in reality it is rather call to apathy. 'Are social-political and economic relations of modernity a thing of the past?' is a fundamental question that much of the indigenization debate has failed to address. Modernity has never been a well-defined term within social work debates. Institutions and systems that were prevalent in this ill-defined epoch are still operational and dominant. Capitalist modes of production and the geopolitics of imperialism are still driving forces

behind oppression, exploitation, and war. To claim that these systems do not exist or that they belong in a past era, can only lead to further confusion with regards to the nature of oppression and discrimination within 'indigenous' peoples experiences. As Ferguson and Lavalette (1999: p. 29) explain

> It is not at all clear why the absence of 'universal truths' should be celebrated. For if all dis- courses are equally valid, then presumably there is no basis for distinguishing between the account of the racist to his black victim, of the abused wife to her abusing partner, or of biomedical psychiatry to a mental health users' movement.

Uncritical celebrations of the 'cultural differences' over structural systemic inequalities, do little justice to the local and global movements, which engage with the struggle against neoliberalism. It would be an oversimplification merely to suggest that international social work was imposed from colonial and imperial powers and as a result oppresses all sections of local populations *equally*. In fact, most of the mainstream international social work literature unwillingly indicates the opposite; colonial social work was welcomed by certain social classes of the population and loathed by others. For example, Ioakimidis (2011) explains how the import of social work in Greece received active support from the Greek ruling classes and at the same time it was used as a tool to suppress and control the working classes.

> The Greek state welcomed and actively supported the 'transplantation' of the new profession. Queen Frederica personally adopted the project, becoming the main patron of the profession's development (…). Systematic efforts of local and international patrons to transplant Anglo-American knowledge have been historically combined with eradicating existing grassroots welfare networks' (2011: p. 508).

Interestingly, much of social work interventions, which were used within this oppressive process were celebrated as 'indigenous' and 'localized.'

Therefore, the question of class divisions and the role of state interaction with colonial or postcolonial societies are of the outmost importance and cannot be ignored. Most of these societies also experience sharp internal divisions primarily related to social class and race/gender. Celebrating them as 'united in their cultural uniqueness' would be a gross idealization and oversimplification of the complex sociopolitical antagonism embedded in these societies. Such divisions became deeper during the colonial/imperial era while local elites were nurtured by global imperialism and the metropolis of Western capitalism. Many states created in postcolonial period often mimicked the colonial power relations simply masking oppression under the veil of nationalism or 'indigenization' (see Midgley, 1981).

Within this context, social work has been used as a tool to promote specific state-sponsored policies, which are often oppressive and stigmatizing. Jordan, Saudi Arabia, and Egypt offer characteristic examples of such contradictions. International social work literature routinely celebrates the advancement of professionalism and localization claiming that the culturally relevant forms of social work in these countries has produced a much needed and progressive profession (see Al-Makhamreh and Sullivan, 2012; Villa, 2011). However, such literature primarily focuses on the cultural aspects or the need for 'professionalization' and it ignores the vast inequalities within these countries reflected on the ongoing struggle for change, which has inspired the Arab Spring.

Despite the 'evolution' of imperialist intervention, its core mission still remains intact: geopolitical struggle for influence and exploitation of global markets, natural resources, and workforces. Over past decades, the emphasis of imperial interventions has shifted away (but not completely) from open military invasions to a more sophisticated form of violence; this of forced 'liberalization of economies' and free market reforms. As Callinicos (2009: p. 9) explains

> the imperialism of free trade is exactly what the EU, as well as the US, have been pressing on other countries, particularly since the establishment of the World Trade Organization.

Inevitably, First Nations cannot be seen as unaffected from this process. The idea that, somehow, culturally relevant social work can facilitate the 'liberation' of these populations is futile unless we identify the nature of the institutions and systems from which oppressed groups should break free. 'Naming the beast' has long been a taboo issue within social work literature. However, without clearly exposing the widening inequalities and stark injustices, which are a direct product of neoliberal capitalism, social work would be powerless in the struggle for the liberation of the oppressed peoples; part of which are First Nations communities. A focus on 'culture' and 'diversity' only obscures the common experiences of the working classes and oppressed groups. Creating indigenous 'islands of independence' within capitalist and oppressive states is an impossible mission. The example of Latin America indicates that an isolated indigenous movement cannot prevent capitalist expansion in to the land, natural resources, culture, and autonomy of the First Nations. The struggle of the indigenous people of Chiapas in Mexico provides a powerful case. Zapatista Army of National Liberation (EZLN; Zapatistas) have long fought for the autonomy of the indigenous people, attempting to create a space free from state oppression. However, after a long struggle for 'indigenous autonomy' the iconic leaders of the movement admitted that the struggle for indigenous liberation cannot be isolated from the broader movements within Mexico. In 2005, Zapatistas announced a change in their strategy for liberation. In a declaration known as the 'Sixth Declaration of the Selva Lacandona' they declared that a main priority for the movement should be the creation of broader national and international alliances in order to facilitate global anticapitalist struggle.

> We are going to continue fighting for the Indian peoples of Mexico, but now not just for them and not with only them, but for all the exploited and dispossessed of Mexico (...) we are going to go about building, along with those people (…) a program of struggle, but a program which will be clearly of the left, or anti-capitalist, or anti-neoliberal, or for justice, democracy and liberty for the Mexican people.
>
> EZLN, 2006 http://enlacezapatista.ezln.org.mx/sdsl-en/

This example vividly reveals that many of the problems indigenous people face are shared by millions of other oppressed people across the world, but is often ignored by 'indigenization' advocates. In many cases, global issues (poverty, inequality, environmental disasters) affect both social workers and the people we work with alike. Dominelli (2012) has categorically suggested that social work cannot remain indifferent and apathetic to neoliberal policies, which result in continuous oppression, major injustices, and irreversible natural disasters; issues that need to be addressed as interconnected and not isolated phenomena.

Ferguson and Lavalette (2006: p. 315) have demonstrated that engagement with the broad anticapitalist movement can provide social work with a great opportunity to rethink social work theory and practice and most importantly demonstrate that 'another social work is possible.'

> The injunction from the anti-capitalist movement to think global, act local provides a fresh basis for social workers to actively make the connections between the neoliberal global agenda and their day-to-day experience as social work teachers, workers and clients, and also provides us with the basis for a new, global social work theory and practice.

Historically, social work has been characterized by a major contradiction. It has been developed as means of care for the most vulnerable people in our societies while being used as a tool for social control, targeting the working classes and demonizing the poorest people. This contradiction, which is also evident in much of international social work, indicates that claims about social work as a profession *inherently and unconditionally* committed to social justice are only empty words unless such language leads to specific and tangible actions. Recognizing this dual nature of social work is only the first step in engaging with emancipatory practice. Developing alliances and *acting* for social change is the next and foremost one.

Neoliberalism

Abstract

This article teases out the concept of neoliberalism as ideology, as a form of governmentality, and as a policy paradigm. It provides a brief history of neoliberalism and then discusses the consequences of neoliberalism in respect of unfair trade, the destruction of domestic production and markets, poverty, and inequality. It concludes with the argument that despite the ideological hegemony of neoliberalism, the current crisis and trends of global social justice movements, which social workers can be engaged in, hold potential to create alternative socioeconomic and political systems in support of a more just world.

Introduction

Neoliberalism has its ideological roots in classical liberalism articulated by early theorists such as John Locke, Adam Smith, and David Ricardo and in the twentieth-century theories of Friedrich von Hayek and Milton Friedman (Harvey, 2005; Pierson, 1991; Steger and Roy, 2010). The neoliberal revolution was consolidated during the regimes of Margaret Thatcher in the United Kingdom and Ronald Reagan in the United States from the early 1980s onward. A related significant event during this period was the opening up of the economy of China, the world's emerging superpower, by Deng Xiaoping in 1978. According to Harvey (2005), events in the United Kingdom, the United States, and China during this period "spread and reverberated to remake the world around us in a totally different image" (p. 1). The breakdown of Soviet communism also played a decisive role in entrenching neoliberalism as the dominant ideology. The past few decades have witnessed the increasing dominance of neoliberalism as discourse and practice on a global level, which has remolded health, education and welfare, and global flows of finance, trade, and labor (Abramovitz and Zelnick, 2010; Schram and Silverman, 2012; Sewpaul, 2008; Rowden, 2009).

Classical liberalism is characterized by a global laissez-faire that holds the market to be sacrosanct, self-regulating, and entirely rational. This was the appeal of Adam Smith's idea that "markets and the pursuit of self-interest would lead, as if by an invisible hand, to economic efficiency" (Stiglitz, 2006: p. xiv). Referring to contemporary neoliberalism, the collapse of markets; the implosion of the American financial system, beginning with the subprime mortgage crisis that began in August 2007; and the bail-out of banks, Gray (2009) reiterated his belief of 1998 that: "Today's regime of laissez-faire will be briefer even than the *belle époque* of 1870 to 1914, which ended in the trenches of the Great War" (p. xii). Obama's (2009) inaugural address in which he warned that, "without a watchful eye, the market can spin out of control" also made some people believe that the end of neoliberalism was imminent. Yet, the "world failed to shake the 'Washington Consensus'" (Bond, 2010: p. 59) – a consensus between the International Monetary Fund (IMF), the World Bank (WB), and the United States Treasury that fostered fiscal austerity, privatization, and market liberalization (Stiglitz, 2006) that are defining features of neoliberalism. However, there is now hope as the majority of the world's dispossessed (symbolically represented as the 99%) is reacting to global capitalism as seen in the recent Arab spring, the Occupy movement, and protests in many parts of the world. This article teases out the concept of neoliberalism, provides a brief history of it, and then discusses the consequences of neoliberalism. It concludes with the argument that despite the ideological hegemony of neoliberalism, the current crisis and trends of global social justice movements hold potential to create alternative socioeconomic and political systems in support of a more just world, which constitutes a central goal of social work education, research, and practice.

Conceptualization of Neoliberalism

Neoliberalism refers to a combination of socioeconomic and political discourse and policy choices based on the values of an unregulated market; the rarefaction of individual freedom and choice; as well as the faith that market fundamentalism, and not state intervention, would promote economic growth, efficiency, progress, and distributional justice, primarily through trickle-down effects. Harvey (2005) defines neoliberalism as "a theory of political economic practices" (p. 2), rather than an unadulterated political ideology. Although neoliberalism has its roots in classic liberalism, it has come to span diverse political leanings and is associated with center-left politics, moderate right-wing conservatism, and autocratic dictatorships, embraced by and/or imposed on almost all countries across the globe. The author draws on the works of Larner (2000) and Steger and Roy (2010) to conceptualize neoliberalism as an ideology, as a form of governmentality, and as a policy paradigm. These dimensions are mutually constitutive and overlapping.

Neoliberalism as Ideology

Duménil and Lévy (2011) maintain that the neoliberal revolution was engineered by class and imperialist objectives, serving the interests of a privileged minority and a few powerful countries, with the United States occupying a unique

hegemonic power. They argue that ideology was not the engine of the neoliberal revolution but that "the hegemony of the upper classes was deliberately restored […] A neoliberal ideology emerged, the expression of the class objectives of neoliberalism" (p. 18). Whether a precursor to and/or an outcome of the neoliberal revolution, ideology has come to play a huge role in its reproduction. While the crisis that began in 2007, with the crash in October 2008, held the potential to create cracks in the consciousness of people about the moral and pragmatic limits of a system regarded as inviolate (Sewpaul, 2008), the opportunities seem to be lost. Although Stiglitz (2006) claimed that there is little intellectual defense of market fundamentalism left, a claim supported by a reading of the vast body of literature that almost unanimously speaks of the negative consequences of neoliberalism, there is yet a marked failure to disrupt the Washington Consensus. Given the power of ideology, the disjuncture between popularly held neoliberal values and empirical data, and the lack of political debate on neoliberalism in mainstream politics, this is understandable.

Fortunato Jr. (2005) described the "manufacture of consent" (p. 4) by the mass media that serves the interests of the corporate world and political elites and that ensures that capitalism succeeds through ideological control of consciousness designed to make us believe that neoliberalism is in our interests and is inevitable. Neoliberalism was engineered and gained ground primarily on account of the lure of the language of liberal theory with its emphases on individualism, ownership, choice, flexibility, and competition that mask "the grim realities of the restoration or reconstitution of naked class power" (Harvey, 2005: p. 119). It is not only the manufacture of consent that is created by the media but also the "manufacture of desire" (Leonard, 1997: p. 37) as the market seduces people into constructing themselves as good consumers where their moral worth is determined by their ability to make the right purchasing choices (Bauman, 1992). Bauman (Bauman and Tester, 2001: p. 87) speaks of the "disguise of the individual's freedom of choice," which is so taken for granted that it "seldom has a chance of being examined and questioned […] an old sinister temptation […] left to be exploited by commercial markets." These views are suggestive of Gramsci's (1977) thesis of ideological hegemony exercised by the state and civil society to control the consciousness of people, not through repression or coercion but by gaining popular consent in the reproduction of class relations.

While most theorists are quick to comment on the dangers of neoliberalism, few are willing to critique the liberal democracy that underpins it. There is a general taken-for-granted assumption of a convergence between the market and democracy, with American liberalism and capitalist hegemony touted as the source of morality and democratic practice, which is furthest from the truth (Amin, 2001; Fortunato Jr., 2005; Harvey, 2005). Samir Amin (2001), a postcolonial writer, cogently raises a number of critical questions in relation to liberal democracy and neoliberalism, concluding that "Convergence theory – the notion that the market and democracy converge – is today pure dogma with much of the talk about democracy reflecting the imposition of policy makers who have usurped power in the United States" (p. 9). Gray (2009) declares that "democracy and the free market are competitors rather than partners" (p. 213), a view supported by Stiglitz (2006) who proclaims that neoliberal globalization is not consistent with democratic principles.

Citing several groups of power elites that serve as the main advocates of neoliberalism Steger and Roy (2010: pp. 11–12) argue that: "These individuals saturate the public discourse with idealized images of a consumerist, free-market world [...] neoliberal decision-makers function as expert designers of an attractive ideological container for their market-friendly political agenda."

Neoliberalism does not get reproduced in a vacuum. We are all complicit. "We all consume […] we all participate in hierarchies of race, class gender and privilege. No one is a pure victim in this economic system, though almost everyone is ultimately a loser" (Haiven, 2011: p. 1). Harvey (2005) describes how neoliberalism penetrates daily consciousness so much so that it is normalized and naturalized, and it is considered necessary for social order despite the gross inequalities and poverty that it engenders.

Neoliberal Governmentality

The treatise on neoliberalism as a mode of governance borrows from Foucault's concept of *governmentalities* that provides a means of understanding the relationships between knowledge, power, and technologies of the self (Foucault, 1984; Leonard, 1997; Lemke, 2002). From this perspective, neoliberalism refers to "a political rationality that tries to render the social domain economic and to link a reduction in (welfare) state services and security systems to the increasing call for 'personal responsibility' and 'self-care'" (Lemke, 2002: p. 203). While neoliberalism guarantees personal and individual freedom, each person is held responsible for his or her own actions and well-being. Thus, poverty and hardships are seen as personal failings rather than being attributed to any structural barriers to unemployment and the consequences of exclusions based on race, class, caste, gender, and/or disability. Steger and Roy (2010) assert that:

> A neoliberal governmentality is rooted in entrepreneurial values such as competitiveness, self-interest, and decentralization [...] Rather than operating along more traditional lines of pursuing the public good (rather than profits) by enhancing civil society and social justice, neoliberals call for the employment of governmental technologies that are taken from the world of business and commerce. (p. 12)

Thus, along with neoliberalism, there is entrenching of new managerialism into all spheres of life, including social work and welfare. New managerialism emphasizes getting the job done, with checks and balances in the shortest space of time as well as with the imposition of economy, efficiency, and effectiveness manifesting in such tangibles as performance measurement, inputs and outputs, outcomes, and targets (Dominelli, 1996). One example of this, in the South African context, is the Financing Policy for Welfare, which speaks of business plans, contracts, affordability, efficiency, outputs, performance audits, outsourcing, venture financing, and service purchasing, thus effectively reconstructing users of welfare services as customers (Sewpaul and Hölscher,

2004). This trend, replicated in many parts of the world, found its origins in Britain and the United States. The 1989 Community Care White Paper in Britain (cited in Sewpaul and Hölscher, 2004) promoted choice, flexibility, and innovation, which was to be achieved through a prospering private welfare sector and outsourcing of government services. The introduction of competition between providers is aimed at increasing value for money, efficiency, accountability, and quality of the services provided. Banks (2011), writing within the British context, observes an intensification of "procedures, measurement and centrally defined targets" (p. 10) and the adoption of depersonalized ethics that focus on predetermined standards, contracts, and procedural manuals. New managerialism relegates the importance of other ethical values such as autonomy, critical reflection, care, equality, solidarity, interdependence, reciprocity, respect, and trust in favor of narrowly defined economic priorities (Bottery, 2000).

Neoliberalism as Policy

As a policy package, neoliberalism is associated with spread of global capitalism and consumerism that has engineered the attacks on, and dismantling of the welfare state (Chomsky, 1999; Harvey, 2005; Steger and Roy, 2010), expressed in what Steger and Roy (2010: p. 14) call the "D-L-P formula," which is deregulation of the economy, liberalization of trade, and privatization of state assets, which provided the ideological basis for the restructuring, privatization, and retrenchment of social policy and welfare programs, and for managerial approaches to social work practice (Clarke, 2007). Neoliberalism is a discourse and practice, which rarefies individual interests where transnational corporations (TNCs) and a few, rich powerful elites dominate the market primarily interested in profit making. Following this individualistic logic, the state uses neoliberal socioeconomic policies to allow it to abdicate its responsibilities in relation to the welfare of its people. Evocative of Foucault's (1984) governmentality and technologies of the self, the most dominant neoliberal discourses in social work and welfare have been on the promotion of self-reliance, the importance of individuals and families taking responsibility for their own well-being, and shifting responsibility from the state to local communities. This neoliberal policy doctrine is reflected in the voice of a manager in the South African context: "The State is an entrepreneur of its own. It must make a profit where it can […]. The state must be minimalist, it must really do the least and the last. Civil society, empowered civil society is to do the most" (Sewpaul and Hölscher, 2004: pp. 84–85), a doctrine that had become quite universal in the 1990s, reflecting the hegemony of neoliberalism. Apart from the use of ideological manipulation that engineered this, there was the use of military force and sanctions, or threats of sanctions by the United States against governments in the developing world that deviated from the US ideal of liberal capitalist democracy (Harvey, 2005; Sewpaul, 2006; Steger and Roy, 2010). In some countries like the United Kingdom, there continues to be the strategic use of budgets and legislation, thus avoiding political discourses on the nature of the welfare state and of social work.

Neoliberalism: A Brief History

There are three distinct periods of lasting and deep structural crises in the history of modern capitalism: the crisis of the 1890s, the Great Depression, and the crisis of the 1970s, with the contemporary crisis of neoliberalism ushering in a new phase (Duménil and Lévy, 2011).

Mid-Victorian England saw the demolition of social markets (which combined a regulated market with issues of social justice, with, for example, universal health care and extensive social security) and the introduction of deregulated, free markets that functioned independently of social needs, based on the theories of classical liberals like Adam Smith and David Ricardo (Gray, 2009; Steger and Roy, 2010) who were convinced that economic difficulties were the consequence of government failures, particularly from state interference. People were seen to be creatures of economic rationality and, in accordance with modernist thinking, as opposed to premodern conceptions of an unquestionable divine order (Howe, 1994), evolved the idea of the human being as subject, "an autonomous self who is the source of his or own action" (Sewpaul and Hölscher, 2004: p. 18), thus imposing no duty on the part of the public to provide, or any right on the part of the destitute to claim any relief.

Gray (2009) argues that the removal of agricultural protectionism, free trade, and the Poor Laws of 1834 formed the cornerstones of the unregulated market of mid-Victorian times that has influenced all subsequent neoliberal policies. The Poor Law Act of 1834 was one of the most demeaning and stigmatizing pieces of legislation based on *laissez-faire* ideology, reflected in the activities of the nineteenth-century charities, particularly that of the Charity Organisation Society whose activities "rested on a belief in moral character as the decisive feature in people's circumstances – no structural issues of power, unemployment or marginalization entered the moral calculus" (Clarke, 1993: p. 9), hence "individuals were solely responsible for their own welfare" (Gray, 2009: p. 9). The *laissez-faire* ideology reduced the role of the state to that of "night watchman" (Steger and Roy, 2010: p. 5) where the state takes responsibility only for the most basic aspects of public order, and it entrenched casework as the basis of social work while marginalizing the more structural approaches to the profession, as reflected in the work of the Settlement House Movement.

This *laissez-faire* governance was legislated out of existence from the 1870s onward and, by the end of World War I, markets had become, in the main, reregulated in the interests of public health and welfare. However, individualism and free trade characterized Britain until the Great Depression of the 1930s that paved the way for Keynesian economics underscored by egalitarian or embedded liberalism, which held sway from the mid-1940s until the 1970s (Gray, 2009; Stiglitz, 2006; Steger and Roy, 2010). This was not the product of a natural evolution. Leonard (1997) posits that the political masses played a central role in establishing the Keynesian welfare state in the West, including the United States, although working class consciousness was weaker and more transitory there than in the social democracies of Europe. Keynesian egalitarianism involved state intervention, regulation of the market, the involvement of organized labor to promote full

employment and growth, and some state ownership of crucial national enterprises like railroads, public utilities, and energy companies (Keynes, 1933). Keynes in 1933 (unpaged) argued that, "Ideas, knowledge, science, hospitality, travel – these are the things which should of their nature be international. But let goods be homespun whenever it is reasonably and conveniently possible, and, above all, let finance be primarily national." The salience of his reflections for our contemporary world is expressed in the following:

> Experience accumulates to prove that most modem processes of mass production can be performed in most countries and climates with almost equal efficiency [...]. National self-sufficiency [...] though it costs something, may be becoming a luxury, which we can afford, if we happen to want it.

Karl Polyani also made significant contributions to economic thinking during this period. In 1944, combining issues of economic and environmental justice, he prophetically wrote: "To allow the market mechanism to be the sole director of the fate of human beings and their natural environment [...] would result in the demolition of society" (Polyani, 1957: p. 73). Polyani, like Keynes, believed that sustainable economic relationships needed to be embedded in a framework of regulations, institutions, and social norms.

In the three decades following World War II, Keynesianism, which inspired the American New Deal, the British welfare state, and the Scandinavian Social Democratic welfare model, produced impressive economic growth, low inflation, high wages, and exceptional levels of human well-being and social security. The benefits of Keynesianism, however, eluded most of Africa (Harvey, 2005), which continued to be the biggest loser throughout history and as neoliberalism intensified into the 1990s. Keynesianism came to a halt with the economic crises of the 1970s, with the oil shocks that raised the price of petrol, and induced high inflation and rising unemployment (Harvey, 2005; Steger and Roy, 2010; Stiglitz, 2006). The structural crisis of the 1970s allowed for the reassertion of the dominance of finance (Duménil and Lévy, 2001) revitalizing the earlier creed of classical liberalism under conditions of globalization.

The welfare state in Britain was one of the casualties of the imposition of IMF conditions in 1976 when Britain borrowed US$3.9 billion. The loan came with a heavy price as it introduced policy changes away from full employment and social welfare toward inflation and public expenditure controls (The Cabinet Papers 1915–82). The early 1980s saw the consolidation of first wave neoliberalism, characterized by conservative *Thatcherism* and *Reaganomics*, based on reducing taxes, liberalizing exchange rate controls, deregulation, privatization, and diminishing the power of labor unions, "interlaced with the geopolitical imperative to stop the spread of communism and socialist developmentalism in the Third World" (Steger and Roy, 2010: p. 47), directed primarily at the maintenance of US hegemony through its imperialist roles in the WB, the IMF, and the economies of Latin America, Africa, and Asia (Stiglitz, 2006; Gray, 2009). The introduction of structural adjustment policies and programs, the changes in the US monetary policies toward price stability before full employment, and their associated debt crises produced untold burdens for Third World countries (Stiglitz, 2006; Duménil and Lévy, 2011): "A strategy for development [...] transformed into an actual catastrophe by a decision emanating [...] within leading capitalist countries, with a total indifference for the hardship imposed on the Third World" (Duménil and Lévy, 2001: p. 595). Second-wave neoliberalism has been identified with the policies of Tony Blair and Bill Clinton, that began in the 1990s and sought to strengthen "social solidarity without dropping the neoliberal ideal of market-oriented entrepreneurship" (Steger and Roy, 2010: p. 50), with a corporate-led globalization that entrenched further inequalities within countries and between the North and the South (Sachs, 2005; Saul, 2006).

Despite its success, Keynesian economics was vilified by classical liberals like Von Hayek and Milton Friedman, whose doctrines dominated the 1944 Bretton Woods conference, which saw the introduction of a system of free trade with fixed exchange rates tied to the US dollar and the establishment of the International Bank for Reconstruction and Development, later renamed the WB, and the IMF (Harvey, 2005; Stiglitz, 2006), initially designed to provide loans for Europe's post-war reconstruction but later expanded to fund various industrial projects in developing countries. The General Agreement on Tariffs and Trade (GATT) was established in 1947 in order to enforce multilateral trade agreements. In 1995, the World Trade Organization (WTO) was founded as a successor to GATT.

In the mid-twentieth century, given that national economies were still relatively closed, governments were able to regulate capital movements, which allowed for a period of relative stability and economic growth that enabled the implementation of Keynesian policies that formed the structural basis of the welfare state (Sewpaul and Hölscher, 2004). But following the recession, in 1971, the United States denounced the fixed exchange rate linked to a fixed gold price, a move followed in 1973 by the introduction of flexible exchange rates and the abolition of capital controls by the United States in 1974, followed by Britain in 1979, and by the early 1990s, most of the other 32 Organisation for Economic Cooperation and Development (OECD) countries (Pierson, 1991). The increase in international trade provoked greater financial speculation and fluctuation of exchange rates, with a steady growth of TNCs. These developments altered the economic context within which the welfare state operated in the context of OECD countries, yet they failed to stem the recession that they were aimed at addressing. Pierson (1991) avers that: "Governments throughout the developed West were simultaneously failing to achieve the four major economic policy objectives – growth, low inflation, full employment and balance of trade – on which the post-war order had been based" (p. 145). With monetary policy increasingly being set by the WB, the IMF, and the United States; the ability of capital to move freely; and the growing presence of TNCs that provided capital with an exit option from one national economy to another, the bargaining power of governments was weakened. Yet, the neoliberal agenda was and continues to be a product of strong governments and cannot function without them.

The attack on the World Trade Center on 11 September 2001 led to another phase where the profoundly "anti-democratic

nature of neoliberalism [is] backed by the authoritarianism of the neoconservatives" (Harvey, 2005: p. 205) and where neoliberal discourses are increasingly tied up with the penalization of poverty (Wacquant, 2001) and with antiterrorism and Islamophobic discourses. On 11 September 2001, radical Islamic forces attacked what they considered to be the symbols of economic oppression – the World Trade Centre and the Pentagon in the world's most neoliberal society. Steger and Roy (2010) rightly concluded that "Bin Laden articulated a criticism of neoliberal market globalism that was shared by opponents of neoliberalism across the Left/Right ideological divide – though the principles and horrific methods of al-Qaeda have been unambiguously denounced by the leaders of the global justice movement" (p. 123). Despite growing inequality and crises engendered by neoliberalism, and the global manifestations of resistance against it, neoliberalism endures largely on account of the taken-for-granted assumptions that are reproduced among people on a daily basis.

Consequences of Neoliberalism

The current crises, which is seeing marked decreases in the living standards of people, has reverberating effects in all parts of the globe, as reflected in the crises of Wall Street, the deepening of the Eurozone crisis, the economic slowdown of some of the Asian countries including India and China, and the entrenching of uneven development and greater inequality within and across countries. Duménil and Lévy (2011) contend that, as a class project, neoliberalism has been exceptionally successful as it has worked in the interests of privileged minority capitalist classes with the divides between the rich and the poor having deepened. Neoliberalism has contributed to distorted development between the North and the South, to greater levels of inequality within nation-states, to the further marginalization of women and to a greater feminization of poverty, especially among Black women (Dominelli, 2002; Gibson, 2009; Lara, 2011; Sewpaul, 2005; Stiglitz, 2006; Gray, 2009; Steger and Roy, 2010). The World Commission on the Social Dimensions of Globalization (2004) concluded that the levels of global imbalances were "morally unacceptable and politically unsustainable" (p. x), while some authors like Dominelli (2012) and Nixon (2010) warn that the great threat is also against environmental sustainability. In a survey of 73 countries, the Commission found that apart from South Asia, the United States, and the European Union, unemployment increased between 1990 and 2002, with global unemployment reaching a high of 185.9 million, and that 59% of the world's people were living in countries with growing inequality.

While countries in Africa, Asia, and Latin America have long been the biggest losers within global capitalism with austerity measures imposed as conditionalities of structural adjustment programs (Dominelli, 2008; Rowden, 2009; Bond, 2005; Stiglitz, 2006; Gray, 2009), patterns of capital accumulation and consumption are now becoming more complex, with many of the rich core capitalist countries now being subject to stringent austerity measures. There are new configurations of global power with, for example, a growing Chinese imperialism that challenges the hegemony of the United States. Also, while many companies have been relocating production to low-wage countries for many years, India has become very successful in attracting high-skilled jobs in computer programming and customer services. The North–South divide is giving way to a new international division of labor where the "familiar pyramid of the core-periphery hierarchy is no longer a geographic but a social division of the world economy" (Hoogvelt, 1997: p. xii). The current manifestation of these is the rising levels of unemployment and inequality and the severe austerity measures sweeping across the globe, with the United States and several European countries like Italy, Greece, Portugal, Britain, and France being extremely hard hit. In the United States, between 2000 and 2008 household incomes declined 1%, while corporate profits rose 70%; the gap between the rich and the poor is higher than at any time since 1930; and the rates of poverty and those living without health insurance has increased by 20% (Nixon, 2010). Economic growth in itself does not translate into a better life for the majority of people, and the 'trickle-down' notion of capitalism has proved to be a myth. The International Labor Organization (ILO, 2009) predicted that the crisis would wipe out at least 20 million jobs by the end of 2009, bringing global unemployment to an unprecedented number of over 200 million.

Accompanying neoliberal policy choices are the weakening of trade unions and labor power; tax cuts for big business and the rich; the erosion of meaningful and egalitarian democracy; cutbacks in state expenditure in sectors such as health, education, and welfare; the relocation of labor to areas of least production costs; and the creation of sweatshops and economic processing zones that compromise workers' rights (Gray, 2009; Stiglitz, 2006; Klein, 2000; Sewpaul, 2006; Steger and Roy, 2010). Trade liberalization and unfair trade has often resulted in massive imports, which undermine local production and prices, and increased unemployment, which places enormous strains on poor people, and contributes to children dropping out of school, women and child trafficking, engaging in dangerous work, starvation, and xenophobic outbursts, issues that social workers engage with on a daily basis. The WTO remains a site of marked resistance on account of unfair trade practices, with the US government using it to protect the market for its multinational corporations with devastating effects on smaller-scale business within the developing world (Gray, 2009; Nixon, 2010; Stiglitz, 2006; Steger and Roy, 2010). The subsidies, what Nixon (2010: p. 260) calls *perverse subsidies* that amount to about US$2 trillion a year, include subsidies from rich country governments like the United States, Europe, and Japan that produce cheaper agricultural imports against which farmers in the developing world cannot compete. This practice exposes the hypocrisy of rich countries that argue no subsidies for agricultural products while doing precisely that in their own countries. Another player on the global bloc, threatening domestic production and employment, is China, with an influx of Chinese trade across the globe setting ablaze anger at the destruction of domestic livelihoods (Reuters, 2012). Local producers cannot compete against a range of cheap Chinese imports of clothes, shoes, toys, crockery, and electronics. Chinese goods accounted for 18% of South Africa's imports in 2012, up from 2% in 1995. With the

Eurozone crisis and a declining European market, China has been increasingly turning its trade interest to Africa, with Africa now accounting for about 70% of the revenue of some Chinese companies (Reuters, 2012).

With growing intolerance for lack of government regulation, people are taking measures into their own hands with violence and threats of violence. One Malawian merchant was reported to have said: "One day there will be blood" (Reuters, 2012: p. 13). In South Africa, xenophobic attacks, linked to socioeconomic deprivations, has seen blood and this seems to be spilling over to Chinese migrants. In November 2011, four Chinese were murdered in South Africa (Reuters, 2012). In August 2012, Kenyans protested with placards that said: 'Chinese must go.' If no attempts are made to regulate trade, it is likely that there will be increased backlashes against cheap Chinese imports. Yet, political leaders go against their own professed understandings. In July 2012, Jacob Zuma in Beijing talked about the importance of exercising caution "when entering partnerships with other economies" and he said that the trade relationship was "unsustainable in *the long term*" (Hook, 2012: p. 1, my emphasis). But it is in the *immediate and short term* that people have to feed, clothe, educate, and care for themselves and their children. The consequences of these discourses and policies for social work practice are self-evident, as social workers are at the forefront of dealing with the various manifestations of poverty and inequality.

Conclusion

The austerity measures imposed by the WB and the IMF and liberalization of trade continue to have devastating effects upon people, culminating in the current neoliberal crisis, which heralds a new multipolar world with the emerging economies of China, India, and Brazil being less dependent on the United States (Duménil and Lévy, 2011), and which has generated a range of oppositional movements. From small-scale protest actions in various parts of the world to the Arab Spring and the international Occupy Movement, lies the core-underlying theme of citizen intolerance of political authoritarianism, poverty and inequality, and exclusion in its various forms (Tormey, 2012; Wight, 2012). However, whether or not the current neoliberal crisis will allow for a transition toward a new world order beyond neoliberalism is open to question. Steger and Roy (2010: p. 137) predict that if the crisis continues or deepens "both third-wave neoliberalism (of a more moderate kind than its two predecessors) and a global new deal (built on Keynesian principles) are distinct possibilities for the second decade of the twenty-first century" (p. 137), while Duménil and Lévy (2011) are optimistic that the crisis might "favor a transition evocative of the New Deal" (p. 333). Given the hegemony of neoliberalism and its entrenched institutions and practices in favor of capitalist elites, who are not willing to give up their privileged positions, this will require a very strong counterhegemonic discourse to neoliberalism, envisioning another and a better world based on egalitarianism and emancipatory politics (Stiglitz, 2006; Nixon, 2010) and ensuring that popular global justice movements continue the pressure in challenging global capitalism. The hope for a better world is borne out of the ongoing struggle of the Arab revolution and in people becoming aware of the legitimating power of neoliberal capitalism, as seen in the international Occupy Movement.

Neonatal Bonding

Aldo B Lucion, Universidade Federal do Rio Grande do Sul (UFRGS), Porto Alegre, Brazil

© 2015 Elsevier Ltd. All rights reserved.

Abstract

'Bonding' and 'attachment' characterize affiliative behaviors of the mother–infant interaction. These behaviors are crucial for the survival, providing the innate needs, and development of the infant in the interaction with the environment and sociability. Neonatal bonding involves a particular neuroendocrine milieu in the infant and the mother. Both infant and mother are hyporesponsive to stress, a condition that seems necessary for the approach and bonding. In rats, olfactory learning is the basic mechanism for the infant attachment to the mother. The maternal behavior would be the reciprocity to the infant needs. Oxytocin and vasopressin facilitate social recognition through the olfactory bulb. In rodents, oxytocin is highly involved in several social interactions, including social recognition, pair bonding, and maternal behavior. Neonatal bonding seems to establish the basic parameters for later social interactions.

Definitions: Bonding and Attachment

The neonatal period is a very particular moment in the lives of the mother and the infant. 'Bonding' is defined as the formation of a close personal relationship (as between a mother and a child), often through frequent or constant association (Webster's Ninth New Collegiate Dictionary Merriam-Webster 1991). According to the online Dictionary Thesaurus, maternal–infant bonding is the attachment that forms between an infant and its mother beginning at birth, and this bonding "influences the child's psychological and physical development."

In the human literature, the concept of mother–infant 'bonding' was used in *Maternal–Infant Bonding* by Klaus and Kennell (1976). This publication had considerable public impact and was controversial among neonatology scholars and professionals. The authors' primary concepts were based on animal studies that described sensitive periods in which certain behaviors were most likely to be formed (Bateson, 1979). It was proposed that in humans, there is a sensitive period necessary for the establishment of the bond between mother and infant, and this period extends to a few days after delivery. In some species, such as sheep, there are narrow time windows when the mother–infant bonding takes place. According to these ideas, infant bonding involves innate attachment mechanisms. Bonding defines a special social relationship; however, it does not reveal the full nature of the attachment (Crouch and Manderson, 1995).

The proposal of a specific period and stimuli that trigger a behavioral pattern has ethological roots. The concept of parent to infant 'bonding' has broad application, involving emotions between the mother or caretaker and the infant that are triggered by specific stimuli during a sensitive period; these emotions exert long-lasting effects on the future social interactions of the infant. The triggering stimulus is the skin to skin mother–infant contact. Should this bond be prevented by some interference, the infant may develop psychopathologies (Higashida et al., 2010; Jaffee and Price, 2012).

Studied by Nobel Prize ethologists K. Lorenz, N. Tinbergen, and K. von Frisch, the imprinted behaviors and instincts of animal species influenced the concept of human bonding. The classic picture of K. Lorenz being followed by a flock of geese is emblematic; he was the first figure that appeared after the eggs hatched. Further, several studies on imprinted behaviors revealed maternal features that trigger the infant behavior. Naturally, those features of the mother's body are characteristic of a particular species, and thus, the imprinted behaviors are species specific. Preprogrammed behaviors need a specific stimulus to be activated. In the natural world, imprinting decreases the number of individuals approached by the infant. It can also influence other aspects of sociability such as preferences for social interaction (Bateson, 1979). 'Sensitive' learning periods are also described for song learning in birds. Song learning is necessary for social communication and interaction. Learning species-specific songs is essential for the development of birds (Nelson and Marler, 1994). This learning process involves important neuroanatomical changes and synaptic plasticity that incorporate new song-related neurons (Nordeen and Nordeen, 1990).

In the literature, the terms mother–infant attachment, mother–infant relationship, and maternal–infant bonding are used interchangeably. Bonding and attachment may be linguistically synonymous, but the definitions and characterizations of attachment are predictive of future development, while bonding is an affective state between a pair (Bicking Kinsey and Hupcey, 2013).

'Bonding' and 'attachment' characterize affiliated behaviors in the interaction of a mother and infant. Bowlby introduced the concept of attachment (Bowlby, 1969). Attachment is a set of behaviors involved in the interaction between the neonate and the caretaker, usually the mother. This behavioral pattern is crucial for the survival, innate needs, development, and sociability of the infant. Furthermore, these behaviors are required for the infant to learn how to interact with the environment. Bowlby conceived this pattern as an internal working model, which is based on the internal representation of the environment. According to Bowlby, human beings are born with an innate psychobiological system (the attachment behavioral system) necessary for inducing social proximity to the attachment figures. The interactions with the attachment figures are the bases for future emotion-regulation strategies (Mikulincer and Shaver, 2012).

The concept of attachment has been largely used in Psychiatry to analyze and define patterns of the mother–infant relationship. Standardized instruments to operationally define the mother–infant relationship were created. The 'Strange Situation' paradigm was developed by M. Ainsworth et al. (1978), and multiple attachment patterns were defined as follows: (1) secure attachment, in which the infant shows signs that he or she misses the parent but calms down easily and is active in greeting the parent when the two are reunited; (2) avoidant attachment, in which the infant does not cry when separation occurs and ignores the parent when they are reunited; the infant shows an intense interest in the toys around him throughout the procedure; (3) resistant ambivalent attachment, in which the infant is focused on his parent throughout the procedure; the infant alternates between searching for contact and resistance or passivity and is difficult to calm down during the procedure. A fourth type of infant–parent attachment is a disorganized pattern, in which the infant's behavior is confused in the presence of the parent. For example, the infant may show freezing behavior. Another paradigm used in adults to infer attachment-related states is the 'Adult Attachment Interview' (Main et al., 1985), which is highly correlated with the Strange Situation protocol (Botbol, 2010). Thus, the attachment state characterized early in life by the Strange Situation protocol is useful to predict emotional outcomes in adulthood. Moreover, early experiences with attachment figures may also affect the development and maturation of the brain and have long-lasting effects on brain structures and function (Dana and Raz, 2012).

The importance of mother–infant attachment in the development of the infant is highlighted by the 'parent–infant bonding.' Attachment facilitates several practices during maternity that stimulate mother–infant interaction. As an indirect result of the early publication by Klaus and Kennel, research has increased significantly regarding the long-lasting effects of early life environment on the development of offspring. Several experimental approaches have been developed to analyze the mechanisms involved in infant 'bonding.'

Neuroendocrine Basis in Neonatal Bonding

Neonatal bonding involves a particular neuroendocrine milieu in the infant and the mother or caretaker. Mammals have adapted to attach to a caretaker during the neonatal period. This short period occurs after birth and is variable depending on the species. At this stage, pups approach any type of stimulus, including ones that are potentially dangerous. During the critical period, pups do not have a developed inhibitory system; they do not seem afraid. They are also hyporesponsive to stress stimuli. In the mother, hormonal changes occur in preparation for delivery and maternity. Both the infant and the mother are hyporesponsive to stress during this period, a condition that seems necessary for the approach and bonding.

The life of a mammal pup depends on the caretaker. Just after birth, the pups need to maintain the close relationship that they had *in utero*. Thus, pups tend to keep in close proximity to a potential caretaker. Rat pups are stressed by unknown adult males. Their physical presence induces a stress response in the pup, likely due to the smell of the conspecific from an unfamiliar environment. However, other stimuli do not induce aversion in the pups. The reports of abusive mothers are examples of attachment to a nonsupportive caretaker. In this case, an asymmetric relationship is observed. Pups approach the mother, while she behaves in a manner not conducive to the pups' well-being. Nevertheless, pups maintain such relationships.

It is interesting that bonding increases the physical proximity of the animals, including body contact, without increasing aggression. The reduction in physical distance may elicit several aversive reactions. Social proximity may be aversive. From the first days after birth until around postnatal day 12, rat pups show no averseness to the environment. Remarkably, pups may approach devices that deliver electric shocks. They may bond to abusive mothers. In humans, this is also observed. The studies of R.M. Sullivan et al. (Moriceau et al., 2009) clearly show that the amygdala is activated by an increase in corticosterone around postnatal day 12. After this event, the pups do not show olfactory learning to conditioned odors, and the pups begin to separate from the mother.

It is unknown what factors induce fighting or bonding in a social interaction. In both the cases, the animals are in physical proximity to each other; however, the most likely consequence of fighting is the disclosure of the participants, while behavior that induces bonding tends to strengthen and stabilize social contact.

Before one can infer the nature of these behaviors, whether they are innate or learned, one must unravel the mechanisms involved in neonatal attachment. Crucial mechanistic insights come from studies on the olfactory learning mechanism in rats and the discovery of the role of oxytocin in pair bonding. These findings demonstrate how animals can establish long-lasting and stable relationships. Attachment involves complex behaviors between at least two participants. These behaviors are dynamic and adaptable over time, making them more difficult to study. In contrast, the behaviors and mechanisms involved in activities that tend to reduce the proximity of participants, such as aggression, are studied extensively. Thus, the stimuli and neuroendocrine factors that underlie behaviors that increase proximity are just beginning to be addressed.

Oxytocin and Vasopressin

Several studies investigate the neural circuits and hormones related to maternal behavior. The mother is usually the primary caretaker, but the father also impacts the development of the infant. However, few studies analyze the father–infant relationship during the first months of life (Feldman, 2012).

Oxytocin is critical for infant attachment to the mother very early in life. In rodents, oxytocin is highly involved in several social interactions, including social recognition, pair bonding, and maternal behavior (Shahrokh et al., 2010; Young et al., 2001). Breast-feeding studies show that autistic infants breast-feed significantly shorter than control infants. Oxytocin and vasopressin facilitate social recognition through the olfactory bulb. These neuropeptides directly act on the nervous system

regions that are important for social information, and they may "modulate the activity of other neurotransmitter systems to increase the salience of social olfactory cues" (Hammock and Young, 2006). Lack of adequate levels of oxytocin in infants affects brain development, indicating that mother–infant attachment is important for the long-lasting development of social bonding later in life (Higashida et al., 2010). In birds, oxytocin has also been implicated in pair bonding (Klatt and Goodson, 2012).

The role of oxytocin on social behaviors early in life is not fully understood. However, there is evidence that lack of adequate exogenous oxytocin during infancy affects the normal development of the brain in genetically susceptible infants, thereby increasing the risk of autism. It is unclear how oxytocin in milk is transported into the brain through the blood–brain barrier; however, it is well established that breast-feeding is important for infant survival and brain development (Higashida et al., 2010). Vasopressin is another important neuropeptide involved in maternal behavior (Bosch and Neumann, 2011). Both oxytocin and vasopressin facilitate maternal care in lactating rats. In the olfactory bulb, vasopressin modulates the activity of mitral cells during social recognition (Tobin et al., 2010).

Olfactory Learning in Rats

In a series of elegant studies, Sullivan and coauthors investigate the mechanisms involved in the infant–mother attachment in rats. In the rat pup, the mechanism involves brain structures including the locus coeruleus, the olfactory bulb, and the amygdala. Olfactory learning seems to be the basic mechanism of infant attachment to the mother (Moriceau et al., 2009). The olfactory learning mechanism involves the neuroendocrine system in rat pups, which responds to proper environmental stimulation. This neural circuit is activated by maternal odor and is the basis for the attachment of the infant to the mother; this is essential for pup survival. The neonatal olfactory learning in rats involves approach behavior by the pup and the mother and a coincident attenuation of aversion. As in many mammals, this learning process occurs in a specific period. Reduced corticosterone seems to be crucial for the establishment of neonatal bonding. Indeed, after the natural increase in corticosterone that occurs with age, rat pups tend to show behavioral inhibition. At the same time, pups withdraw from the mother and show detachment behaviors, such as environmental exploratory activities. At this time (around the end of the second postnatal week), feeding is not necessarily dependent on the mothers; the pups' eyes have opened, their incisive teeth have erupted, and they can independently forage. Thus, the necessity of a caretaker (usually the mother) naturally decreases with age. However, the early social interactions with the mother appear to shape future social interactions. The author discusses this point later in this article.

In rat pups, licking by the mother stimulates the locus coeruleus, which has a different pattern of firing in infants compared to adults. The locus coeruleus is more active during the first days after delivery, which stimulates the olfactory bulb. The eyes and ears of rat pups are closed until the second postnatal week; thus, olfaction is crucial in the neonatal period to establish mother–infant attachment. However, olfaction is still in development at this age. In the olfactory bulb, noradrenaline from the locus coeruleus activates beta-adrenergic receptors to depolarize the mitral cells. The activation of beta receptors induces intracellular signaling such as phosphorylation of cAMP response element-binding protein (CREB), which is thought to be required for olfactory memory of the maternal odor (Moriceau et al., 2009). The specific odor of the mother that induces infant attachment seems to be in the mother's feces, which increase in volume due the increased food ingestion.

Humans: Mother–Infant Attachment

Similarly to other mammals, the neonatal period in humans is crucial for survival. The attachment to a caretaker figure is essential (Fonagy et al., 1991). Infants display preferences for social stimuli, suggesting the evolutionary pressure of those stimuli. However, the mechanisms involved in mother–infant attachment are relatively poorly understood. Nevertheless, infant approach behavior and nipple suckling also seem to be determined by olfactory stimuli. Reaching the source of milk is the first step of mother–infant attachment. The capacity to initiate sucking varies considerably among newborns. For social bonding to occur, individuals must have a capacity for social recognition, which includes the ability to detect as well as discriminate familiar individuals. Animal and human studies have shown that infants attach to a maternal figure, even if abusive behaviors are perpetrated by the caregiver. It can be inferred that it is better for an altricial animal to remain attached to an abusive caregiver than to receive no care (Raineki et al., 2010).

To analyze infant bonding, it is also necessary to analyze maternal behavior (Stoesz et al., 2013). Infant bonding is an attachment behavior that involves reciprocity by the partner, the caretaker. The mother displays maternal behavior, which reflects the infant's needs. Thus, maternal behavior is essential to trigger infant bonding. The licking behavior and physical mother–infant contact in rats are important maternal behaviors. In humans, the direction of the infant to the nipple to stimulate suckling is an important behavior that facilitates the development of social interactions. Maternal behavior is more than a response to the infant's behavior; mothers tend to induce infant bonding. The mother–infant early social interaction involves active approach behaviors by both the mother and the infant. The behaviors of a neonatal altricial mammal are limited due to the motor developmental stage. Nevertheless, altricial pups are essentially prone to approach behavior. They approach the mother and littermates. In some species, pups emit sounds to attract the caretaker. This step of infant attachment involves approaching behavior of the mother or caretaker. As for olfactory learning in rats and other rodents, maternal odorants seem crucial for this primary interaction. Odorants in the nipple and areola direct the attachment behavior of the newborn. However, there is variability among species and individuals in the establishment of mother–infant attachment. With time, the complexity of the mother–infant interaction increases. Other salient social cues

become important, such as the sight and voice of the mother. These stimuli contain information regarding the feelings of the mother toward the infant, which are important for the quality of the mother–infant attachment. Here again, the behavior of the mother is necessary for timely interaction with the infant and the establishment of a synchronized mother–infant interaction (Feldman, 2007; Reeb-Sutherland et al., 2012; Schaal et al., 2009).

Several mammalian species depend on maternal care to survive during the first days after birth. This vital relationship evolved from a different reproduction strategy. This strategy involves the spreading of large amounts of eggs by the progenitors, and no further parent–offspring interaction is developed. In contrast, mammals deposit fewer eggs but intensely invest in the offspring, although this varies among species. Thus, from the first moments after delivery, the pups interact with the mother. In fact, they must establish this new form of interaction with the mother to survive. In mammals, the mother and infant bond during the uterine gestational period, which in many cases is very long. During the gestational period, the fetus interacts with the mother and indirectly with its environment. The restricted and self-contained uterine environment imposes the first close-contact mother–infant interaction. However, after birth, the perspectives for the newborn increase dramatically. The physical mother–fetus interaction during gestation is replaced by a broader environment. The gestational close-contact interaction with the mother is disrupted and a different one must be urgently established. In some cases, such as in sheep, time is crucial; the mother–infant contact must be established within a few hours after birth, otherwise the mother will reject the newborn. The extrauterine environment offers enormous possibilities to the pup. In contrast to the *in utero* situation, a relationship with the mother has to be established. In some species such as rats, the mother–infant bond must be learned, for example, by an olfactory learning mechanism.

Innateness of Bonding

Some authors characterize 'bonding' as an innate behavior; the mother has a maternal instinct (Minde et al., 1980; Martyn et al., 2012). It would be more important to understand the strategies and mechanisms involved in this vital social interaction for each species. Bonding could be considered an intervenient variable for a situation poorly understood. The question of innateness is a long-standing debate among behavioral scientists. Innateness does not involve learning processes; the behavior is ready to be performed at the moment of birth. The animal is born with fixed action patterns, or 'instincts.' Thus, the infant needs no learning to engage in typical behaviors that occur after birth. For example, pups remain close to and follow the mother. The idea of innate, prewired behaviors is attractive. If these behaviors are innate, then the animals would not need environmental or maternal stimuli. The behaviors would initiate and form before birth. The stimuli to generate such 'innate' actions could occur intrauterus. Studies show that the mother–infant interaction begins before birth. The taste and the food spices eaten by the mother cross the placenta and induce a 'signature' in the fetus. After birth, the pups expect the same taste in the mother's milk, which is a crucial characteristic to identify the mother. In this case, the infant is 'imprinted' by the mother's behavior. The association of the stimulus and the object is an essential element in the learning processes. In mammals, it is quite difficult to separate the mother and infant. The close associative relationship between maternal stimuli and the offspring is strong, before and after birth. The prebirth bonding could infer a prebirth associative learning. In rats, the olfactory learning mechanism in pups is the basis for the infant attachment to the mother. This is clearly a learning process; indeed, the formation of attachment utilizes the main biochemical mechanisms involved in learning, such as CREB phosphorylation in the olfactory bulb.

The reciprocal interaction between the caregiving environment and the infant's genetic variations causes individual differences in infant attachment behavior. Variations in 5-serotonin-transporter-linked polymorphic region may shape how behavioral security or insecurity is manifested. Only a handful of studies have investigated genetic contributions to infant attachment (Luijk et al., 2011; Spangler et al., 2009; Raby et al., 2012).

The interaction between the environment and genetics in the programming of behaviors is increasingly studied. The influence of maternal behavior on the genotype of the mother and child and vice versa are areas of future study in the field. Several studies demonstrate the vulnerability of some individuals to environment stressors (Labonté et al., 2013). The gene–environment interaction is complex. Genes are affected by the environment; this may result in changes in behavior and may increase vulnerability to psychopathologies. On the other hand, genes may also affect the environment. A critic might take the position that beyond such generalizations, this research does not tell us anything one did not know already. The idea that person–environment correlations are important in shaping development has been recognized in developmental psychology and psychopathology (Jaffee and Price, 2012).

Long-Lasting Effects of Neonatal Bonding: Concluding Remarks

Several studies have shown that early life events can determine the personality and physiology of mammals (Sheriff et al., 2010). The early infant–caretaker bonding seems to establish the basic parameters for later social interactions. Infant bonding is the embryonic development of the social brain. Indeed, the experience with the mother in early life seems to shape the relationship of an infant with its own offspring. Studies in rats that display high or low licking behavior are quite conclusive. The pattern of high or low licking behavior is 'copied' from mothers to daughters. Thus, the daughters of high-licking mothers will also be high-licking mothers with their own pups. Memories from early life are long lasting compared to the myriad of other stimuli that humans experience. Indeed, these other stimuli do not seem to impact the brain in the same way as early life stimuli. This is likely related to the critical period during which the animal is most vulnerable to environmental stimuli. Other close social relationships, such as pair bonding, follow the same principle and possibly have the same neuroendocrine

basis. Bonding involves special cognitive procedures that affect specific brain areas, neurotransmitters, and neurohormones. Alternatively, bonding may stem from the same areas and neurohormones as other social behaviors but show a different synchronization of activity. In this case, the structural bases are the same, but they result in different functions. Several studies show the importance of maternal care in regulating the development of offspring. Indeed, the quality and quantity of the mother–infant relationship seem to shape the future social competence and ability of the infant to face stress (Pedersen, 2004).

Whether this transgenerational transmission is true for other behaviors or physiological parameters is not fully known (Shah et al., 2010). For instance, the epigenetic transmission of glucocorticoid expression in the hippocampus is well documented. Thus, epigenetic mechanisms could explain the transgenerational transmission of the bonding phenotype. The expression of a receptor, for instance, the glucocorticoid receptor, may have an important impact on the stress response. However, innate behavior implies the existence of a complex pattern of activities. In mammals, there is no evidence of innate behaviors that are capable of producing a complex social interaction like bonding. Pups are prepared to respond to vital stimuli. Moreover, at this early age, the behavioral repertoire of the pups is restricted. One may hypothesize that the neuroendocrine system of young mammals is directed to specific stimuli necessary for survival after birth. Among the several environmental stimuli that the pups experience at birth, many more than in the uterus, mammalian pups respond promptly to the mother. It is important to emphasize the role of the mother in directing the behavior of the pups. Pups bond to the mother in part because the mother stimulates the infant to develop and deepen the interaction with her.

Nevertheless, mechanisms involved in the mother–infant relationship seem to be unraveling by analyzing carefully human subjects as well as using animal models. The importance of the early-life mother–infant bonding has been clearly demonstrated in programming behavior strategies later in life in several species. In a certain way, the neonatal mother–infant bonding would be an extension of the intrauterine environment enabling a full neural development of the animal in an environment closely related to the one that will be found throughout life. Neonatal bonding occurs in several animal species, not only mammals, indicating its evolutionary importance on the development of a social brain. Most importantly, this early life bonding would be the main reference for future social interaction in which animals tend to approach each other in opposition to inhibitory sociability or even social disaggregation by aggression. The social signs are essential for durable social relationship and also the establishment of social hierarchies, both crucial for the species survival. Neonatal bonding seems to establish the basis for the development of the social abilities. The caretaker, usually the mother, would guide that development, which has to occur outside the uterus in mammals or the egg in birds, in close contact with the environment that the infant will probably face in life. Thus, one may infer that the neonatal bonding has its innate roots and also seems to need plasticity in order to face the variability of the environment. The research challenges are various; however, it seems crucial to understand how the environment 'gets into the skin' of the infant and what are the first, second, third, and '*n*' order messengers that convey environmental information to the brain of the infant. Moreover, the neuroendocrine changes induced by those stimuli are necessary to be stated. With that, the origins of some important psychopathologies would be known and thus better treated.

Neonatal Crying Behaviors

Kathleen Wermke, University Clinics, University of Würzburg, Würzburg, Germany

Abstract

Neonatal crying is far more than an innate biological alarm mechanism employing acoustic signals and reserved exclusively for the communication of emergency and distress. As they have been more closely identified in recent years, the principles of cry melody development allow us to class infant cries with other forms of non-cry vocalizations as essential precursors to language acquisition. The differentiation of cry melodies alongside the parallel development of increasingly finely regulated intensity contours over the first weeks of life distinguishes the crying of human neonates from that of nonhuman primate infants. The latest research indicates a marked divergence between human and nonhuman primate infants in even the earliest stages of vocal development. This makes human infants and their early vocalizations particularly suitable candidates for research on spoken language acquisition.

Crying as a Communicative Behavior

For a long time neonatal crying has primarily been seen as a behavioral state in contrast to other states such as sleep, drowsiness, and wakefulness, and one that points to a physiological state of distress associated with physiological and behavioral changes other than vocalization itself (Wolff, 1987). This behavior, typical of the first months of life, is however done more justice when cries are characterized as a social signal and crying as a communicative behavior. In the first 2 months of life it is primarily crying and fussing that assume a predominant role in the expressive repertoire of the neonate. (Cry intensity may vary between whimpering (fussing), mitigated crying, and vigorous crying. These expressions may differ with regard to their rhythmical features, fundamental frequency and intensity features, as well as to the nature and rapidity of maternal responses that they provoke. However, here the focus lies on the function and general characterization of neonatal crying (and the unpleasant bodily and emotional states it elicits) and a clearly drawn boundary may not be relevant for the purposes of this article. A detailed differentiation can be found elsewhere, e.g., Wolff, 1987; Barr et al., 2000.) The neonate may also produce a few quiet, short non-cry sounds from the beginning of life. The latter play a comparatively minor role in social interaction, however, owing to the affective and communicative power of crying, a feature directly related to its biological function. Beginning in the third month of life, the infant's expressive acoustic repertoire significantly broadens, such that now in stress-free situations pronounced and clearly audible comfort sounds (cooing), capable of eliciting a clear response in the listener, are used to communicate.

As a result of its physical helplessness, the human infant is dependent upon close social contact with its mother from birth. (The term 'mother' is used here to imply the neonate's primary caretaker.) It follows that biological signals would help to facilitate in this interaction. Crying – acoustic signaling – is the most powerful signaling available to the neonate. As a distal cue, it is effective not only in immediate proximity to or physical contact with the mother, as with proximal cues such as smiling and gaze, but also when the mother is outside of the visual range of the neonate or in conditions of darkness. Acoustic signals thus assume a special role in the development of attachment in comparison with attachment-promoting visual signals.

Human neonatal crying is often functionally equated with nonhuman primate infant crying, insofar as both are regarded primarily as 'separation calls,' which function exclusively to minimize distance to the mother. However, this model likely applies to a far greater degree, if not exhaustively, to nonhuman infant crying (Todt, 1988; Bard, 2000). Human neonatal crying has a much broader functional spectrum. It serves primarily interaction-regulating purposes by expressing emotions and feelings (Keller et al., 1996; Falk, 2009; Wermke and Mende, 2011).

Neonatal cries are heavily loaded with emotions. The neonate sends messages regarding his or her sensations, feelings, and wants and these are above all coded in the cry melody. These messages are 'body-near,' in that they immediately express bodily conditions and emotional states, and they are in large part intuitively 'intelligible' to the mother. It is therefore hardly surprising that there exist several diverse approaches seeking, by way of acoustic properties, to grasp the underlying emotional content of an infant's crying and to differentiate, for example, between cries of hunger, pain, and frustration (Wasz-Höckert et al., 1968; Lester and Boukydis, 1985; Wolff, 1987). Over a developmental period of several years leading to full acquisition of the native language, the messages encoded in a child's acoustic utterances will become increasingly complex and differentiated.

A long evolutionary adaptation process has enabled the mother and her newborn baby to be a priori tuned to each other. Characteristics of both infant and mother help shape and ultimately determine their interactions with one another. A 'mistuning' within this biologically preprogrammed system may produce a cumulative feedback effect ultimately leading to behavioral changes on the part of the infant (e.g., extensive or excessive crying, the avoidance of eye contact, or the deliberate turning away of the head) and negative emotion on the part of the mother (e.g., feelings of guilt, failure, and frustration) (Keller et al., 1996). The latter holds all the more true, as the mother is often well-aware that she is the one who more strongly determines the nature and manner of this interaction during the neonatal period.

Crying as Part of the Typical Behavioral Repertoire of all Neonates

Crying belongs to the normal behavioral repertoire of any neonate. This does not mean, however, that all infants cry to the same degree or with the same frequency. As in all forms of human behavior, crying behavior varies between individuals and develops with age. There are several reasons for variations in the amount and daily frequency of crying between neonates. For example, individual personality factors (e.g., temperament, sensitivity to pain, irritability, perinatal and postpartum discomfort experiences), as well as inter-individual differences in brain maturation, may contribute to variability in crying behavior. Apart from general maturational effects, furthermore, all physiological and medical states affect neonatal crying behavior. In this respect, it is not only the amount of crying that may differ between healthy neonates and those neonates who are ill, born prematurely or with certain congenital conditions, or exposed to potentially painful medical treatments or procedures, but also the acoustic character of this crying (Wasz-Höckert et al., 1968; Lester and Boukydis, 1985). This clinical perspective is outlined in more detail below.

Through the process of biological feedback and 'tuning' between mother and child outlined above, maternal personality characteristics and patterns of behavior in relation to the neonate can also influence the amount and frequency of neonatal crying. Observations indicate that the amount and frequency of neonatal crying as well as the response behavior of mothers varies culturally and across a spectrum encompassing irritation, anger, and sympathy (Eibl-Eibesfeldt, 1983; Kruger and Konner, 2010). In pre-industrialized societies, where neonates are often provided with intense physical contact and in which neonatal crying is responded to immediately and by frequent nursing, newborns were found to cry less and rarely in inconsolable bouts (Kruger and Konner, 2010). However, more systematic cross-cultural cry studies, including recorded acoustic data from hunter–gatherer and forager cultures, are needed in order to establish a 'normal neonatal crying curve' or a 'normal amount of daily crying' in neonates cross-culturally. Thus far the extant data are limited, suggesting that claims such as crying of 6.7 h per day during the first 3 days of life of crying is typical, and the mean duration per day for the first 3 months can reach 120 min or postulations as to a peak in the daily amount of crying around 6 weeks of age, should at least not be accepted uncritically. The range of data suggested by several authors, spanning cry periods rarely in excess of 6 min in the first month of life, or 3 min in the second and third months, to cry periods of two to 3 h per day over the first 6 months of life cautions against generalization. (The effort to define the 'normal' amount and duration of neonatal crying was launched by pediatricians faced with cases of excessive crying and related parental complaints. This is, however, a special aspect of cry research that is thoroughly described elsewhere; see, for example, Barr et al., 2000.)

Already in 1987, Peter Wolff pointed out that it is difficult to establish a mean duration or normal quantity for crying. This is because both depend not just upon the neonate and its particular mental state, but also to a significant degree upon maternal behavioral responses, which determine whether crying is terminated "before it [has] run its course" (p. 80).

Anatomical Basis and Neurophysiological Control

The coupled audio-vocal system represents the most developed neuromuscular functional system of the neonatal central nervous system (CNS). Crying may thus represent the most highly coordinated and finely regulated motor behavior available to the neonate. A prerequisite of neonatal cry production is a well-coordinated interaction between respiratory and laryngeal mechanisms. The muscles of the larynx function as a part of the respiratory system before birth, and like all other respiratory muscles they have undergone considerable use prior to birth (Harding, 1984). Crying is produced during the expiratory phase of the breathing cycle; some neonates also vocalize during the subsequent inspiration.

The neonatal larynx features a soft cartilaginous, skeletal structure and a relatively narrow lumen. According to an investigation by Savkovic et al. (2010) in infants between 0 and 12 months of age, the larynx has an average length of 11.9 ± 0.3 mm and an average width of 17.7 ± 0.5 mm. Both measures were significantly correlated with the infants' body length. A layered structure or vocal ligament is absent in the neonate larynx. This and further identified specifics of the fine structure of the human newborn and infant vocal fold mucosa led scientists to conclude that the vocal fold mucosa lack adequate viscoelasticity for phonation and that the newborn glottis hence seems to serve more respiratory than phonatory function. However, the astonishingly vast phonatory range and complexity reflected in neonatal cry properties suggests otherwise, as does the fact that neonates are able to cry loudly and intensively over hours without displaying noticeable signs of exhaustion or even developing aphonia. A comparable performance, involving the prolonged maintenance of a maximum vocal load, would hardly be possible for adults. Through their study of the neonatal larynx, particularly the distribution of hyaluronic acid within the neonatal larynx, Schweinfurth and Thibeault (2008) have contributed to solving this paradox. The differences in the laryngeal structure between neonates and adults seem to explain the neonate's capacity to sustain relatively high-pitched crying and high volumes over a long period of time. Hyaluronic acid, an interstitial polysaccharide, is seen as the primary determinant of vocal fold viscosity and water content. The apparent 'immaturity' of neonatal laryngeal structure thus yields, upon closer observation, a survival advantage by supporting sustained, load crying when necessary. This supports the older findings of Lind and Truby (1965), who, with the help of detailed cineradiographic investigations, demonstrated that the neonate is capable of well-coordinated laryngeal performances.

In order to align subglottic, glottic, and supraglottic functions, all of which are involved in phonation, a comprehensive neurophysiological coordination is demanded. To this end, information is required from several regions of the brain. In human infants, studies of brain function during crying do not exist. Neural circuits mediating crying and their maturation have been identified in animal studies (cf Newman, 2007).

In mammals, the neural structures involved in phonation form an extensive system spanning all levels of the brain (Newman, 2007). Jürgens (2009) described a model of vocal control, based mainly on research in the squirrel monkey, which consists of two hierarchically organized pathways. The first of these controls the readiness to vocalize. It runs from the anterior cingulate cortex via the periaqueductal gray (PAG) into the reticular formation of pons and medulla oblongata, and from there to the phonatory motoneurons. The second pathway was found from the motor cortex via the reticular formation to the phonatory motoneurons. It includes two feedback loops, involving the basal ganglia and the cerebellum, respectively, which provide the motor cortex with information needed to generate final motor commands.

These and other studies challenge the assumption of a so-called 'brainstem model' of crying, which excludes the possibility that structures rostral to the midbrain play a role in cry production (cf Newman, 2007).

Neonatal Crying from a Clinical Perspective

The preceding remarks suggest that the neonatal larynx and indeed the whole phonatory system responsible for crying is not only mature enough for, but also ideally suited to, its function in neonates. The early maturity of this system, the complexity of the underlying neurophysiological mechanisms as well as the high speed at which the vocal control mechanism acts, make neonatal cry properties a suitable indicator for the identification of neurophysiological dysfunctions. In addition to direct studies of the brain, dysfunction in complex cerebral systems can only be identified by studying the performance of the corresponding efference system, such as phonation. Scandinavian pediatricians observed this in the early 1960s and systematically investigated neonatal crying with the then-available technique of signal analysis (Wasz-Höckert et al., 1968; Michelsson, 1971). The value of these pioneering studies cannot be overestimated, even if they were initially centered on the descriptive analysis of crying in neonates already diagnosed with medical conditions. These and a number of more recent studies have shown that, of the numerous theoretically definable signal parameters of a neonate cry, some have proven suitable as risk-markers that most directly reflect dysfunctions in vocal control. These are entities that characterize the sound source (larynx), such as the mean fundamental frequency, the fundamental frequency contour (melody), and related parameters and temporal parameters. As the supralaryngeal structures and their modifying function in vocal production mature, both the importance of vocal tract resonance characteristics and their variability in assessing neurophysiological performance increase. This is nonetheless not to be expected before the third month of life (Wermke and Mende, 2011).

However, clinical cry studies have thus far offered little in terms of new diagnostic information for individual neonates. Apart from the absence in these studies of clinically suitable reference values for the normal range of cry properties among healthy neonates, previous studies have also disregarded the age effect. Investigations conducted in our laboratory have yielded ample evidence for the modification, at times remarkably rapid, of cry properties over the first weeks of life. Additional known factors that can influence cry parameters and which must be taken into account both in the clinical interpretation of cry studies as well as in the establishment of normative values include gestational age, mode of delivery, somatic state (small-for-gestational-age vs appropriate-for-gestational-age neonates), the individual course of the postnatal adjustment phase, neonatal hearing performance, maternal drug abuse, and not least, the influence of maternal behavioral factors. Moreover, in the majority of previous cry studies from a clinical perspective the analyses were based on pain cries, which differ in their typical features from spontaneously uttered cries (see below).

I see at least two clinical areas in which a revival of cry diagnosis would benefit future work. The first of these concerns sensory-neural hearing-impaired infants. A systematic clinical study of changes in cry parameters in hearing-impaired neonates under strong control of all clinical data, including amplification data, may, for example, help to identify neonates with progressive hearing loss or may provide complementary information for an individually optimized treatment from an early age. Secondly, given the complex neural pathways underlying neonatal crying, maturational delays in a single circuit may cause imbalances or dysfunction of the network. In the future it may become possible to evaluate the developmental status of specific brain circuits underlying human neonatal crying.

In any case it will be necessary to establish suitable reference databases of cry characteristics and their range of variability, as well as age-dependent changes in healthy infants, before cry diagnosis can be employed as a clinical method.

Characteristics of Neonatal Cries

The basic acoustical signature of neonatal cries is primarily determined by processes that characterize the sound source (phonation). Because neonate populations worldwide do not differ in terms of the anatomical structures and functional mechanisms of phonation, the essential acoustic attributes of neonatal cries are similar everywhere. Neonatal cries are characterized by a mean fundamental frequency between one and two octaves higher than that of an adult voice. The mean fundamental frequency of spontaneous cries of healthy neonates varies between about 350 and 650 Hz. Investigations as to whether this range is slightly modified in neonates with an ambient tonal language are still pending. Neonatal cries, except pain cries, which are described below, exhibit an undisturbed spectral pattern consisting of a fundamental frequency which varies with time (melody), and its integral multiples called harmonics. Nonstationary frequency spectra provide information on spectral changes over cry time and represent a visualization of the perceived acoustic spectrum (**Figure 1**a–c, right side).

Neonatal cries can exhibit fundamental frequency instabilities, as in the form of sudden jumps of the fundamental frequency (shift) or vibrato-like phenomena. In neonates, these are often signs of a temporarily immature vocal control. Only if they occur repeatedly and over a longer time period may they indicate an at-risk or even pathological condition. It is important to note that this applies only to spontaneous cries that were not elicited by a pain stimulus.

Figure 1 a–c: Melody/intensity contour diagrams of 3-day-old newborns' cries.

The frequency spectra of single cries may also contain subharmonics or noisy elements; both are found in healthy neonates and neonates with medical conditions. Mende et al. (1990) were the first to show that at least some of the phonatory noise phenomena in neonates' crying are caused by nonlinearity in vocal fold mechanics and can be interpreted as low-dimensional chaos. As the distress level increases and crying becomes more intense, these phonatory noise phenomena grow more pronounced, likely a result of the inability of the tiny vocal folds to withstand the enormous subglottal pressure during crying (cf Titze, 1993). Over the first 4 months of life, the neonate learns to avoid these phenomena and the frequency of occurrence of such subharmonic and noise phenomena drastically declines in healthy infants, without, however, disappearing entirely. In subsequent stages of vocal development, noise-like phenomena are intentionally produced where required by the specific features of the native language.

The fundamental frequency contour (melody) of a cry reflects the oscillation pattern of the vocal folds as it varies over time. It is only roughly recognizable on the basis of the contour of higher harmonics in the frequency spectrum, and is therefore best represented in special melody/intensity diagrams (Figure 1a–c, left side).

The melody consists of single rising-then-falling arcs exhibiting a rising contour (a) and a falling contour (b, c), respectively. The corresponding spectrograms are also displayed. In all three examples melody contour is relatively independent from intensity contour in respect to monotony behavior.

The fundamental frequency of a cry is produced through a coordinated interplay of laryngeal muscles. CNS mechanisms must regulate this interplay in order to enable the efference of precisely reproducible melody contours. It is often claimed that neonatal crying merely reflects the infant's respiratory cycle or even represents a reflexive manner of vocalizing in which the infant has lost vocal control. Of course there must be a principal coupling between respiratory activity and laryngeal cry production, but as our research very clearly indicates this is an elastic coupling. Neonates are already capable of an independent control of fundamental frequency and intensity (see Figure 1a–c). The elastic coupling, or the relative independence of melody from intensity, powerfully suggests that neonatal cries are not simply the byproducts of aerodynamic processes. These findings clearly contradict older descriptions that claimed

that cry melody was constrained by the respiratory cycle and emphatically refute the assumption that the crying of human neonates is reflexive and uncontrolled.

In the course of the first months of life, a neonate's increasing mastery of fundamental frequency modulation (melody) develops in close concert with growing control and the intentional regulation of intensity. From around the fourth week of life one can often observe how, in an almost playful manner, melody and intensity contour are woven into the most diverse vocal combinations (Wermke and Mende, 2011). These variations give the impression of a preparatory exercise, in which it is possible that the groundwork is being laid for acquisition of language-specific patterns of accent and emphasis. This decoupling is, alongside observed forms of systematic melody development (see below), an example of the specificity of the human developmental pathway. The investigation of the interplay of melody and intensity contour could itself prove a fruitful area of future research, both in the field of clinical cry research as well as from the perspective of language acquisition. In this area there remain considerable gaps in our knowledge. In conclusion, I would like to underscore that neonatal crying does not only differ in amount and duration, but also in acoustic properties from neonate to neonate.

The Specifics of Pain Cries in Neonates

Crying is a highly effective means by which a neonate can express acute pain. Due to their salience, cry features are used in several pain-scoring systems for neonates. The identification of pain-related specifics of cry properties has been a matter of intensive research. Cries uttered immediately after an acute pain stimulus may be characterized as having an increased mean fundamental frequency, a short rise time of the melody contour up to its maximum, an often very irregular frequency pattern and an extended duration. After the acute phase of pain sensation, the fundamental frequency declines to 'normal' values, cry duration decreases, and cry melody changes its shape from a falling toward a typical rising-falling pattern (cf Wasz-Höckert et al., 1968; Lester and Boukydis, 1985). Thus, cry parameters change with the diminishing of a pain sensation. It is important to note here that there is no single type of pain-stimulated cry (prototypical pain cry), just as there is no single hungry, pathological, or stereotypical 'normal' cry. When one compares across different neonates the first few cries uttered after receiving the same pain stimulus (e.g., heel-lancing), considerable differences can appear in the cry parameters. This is, however, to be expected, owing to the complexity of the underlying neurophysiological mechanisms. One must take account of the uniqueness of pain cries when investigating neonatal crying.

Developmental Changes of Cry Properties: A Special Note on Melody

The first week of life is generally characterized by individual adaption processes. These processes are reflected only marginally in the cry melody pattern of these neonates, however. They are more reflected in the short-time variability of the fundamental frequency (Wermke and Mende, 2011). This points to the particular importance of cry melody among the full range of cry parameters.

Neonatal cry features undergo significant changes in the first weeks of life. Fluctuations in volume or variations in melody or rhythm, as in the insertion of pauses between single melody arcs, can be observed already in the second week of life. The richness of variability among melodic and rhythmic elements is already in these first weeks remarkably high (Wermke and Mende, 2011).

Neonates are particularly sensitive to musical elements. Even in utero, the fetus is especially receptive to prosodic acoustic features, particularly to the melody of human speech. The dense functional coupling of auditory and vocal systems furthermore allows the neonate to actively produce and rehearse melodic-rhythmic elements in his or her own crying from the moment of birth. The early rehearsal of melodic-rhythmic elements appears to be essential for the undisturbed process of language acquisition in the first year of life. We postulated that neonates' melody skills could mean much more than a special acoustic capability; they might even be a language learning imperative (Wermke and Mende, 2011). Adopting this perspective, a young infant's melodic skills should predict that same child's language skills much later, because both reflect the same capacity of language learning.

Our longitudinal studies demonstrated a continuous coherent unfolding of cry melody features during the first 28 weeks of life which we interpret as a developmental program (Wermke and Mende, 2011). We found a relatively smooth unidirectional development from simple single-arc melody structures, prevailing in neonatal crying of the first week of life, to an increasing number of double- and multiple-arc melody structures in cries of the following weeks. Complex cries may consist of two, three, four, or more melody arcs within a single expiratory cry signal, and can be understood as being composed of a concatenation of simple arcs as building blocks. Following this interpretation, melody development is seen as a primitive step in a coding hierarchy creating the first combinatory assemblies of melody arcs, coding emotions, affects, and needs (Wermke and Mende, 2011). This development starts immediately after birth, that is, long before babbling or any symbolic word use occur. This coding is tightly coupled with bodily processes in neonates and is therefore much less arbitrary than the semantic configurations that appear in the utterances of older infants, children, or adults. Melody development in infants' vocalizations lays the groundwork for a later divergence of separate, but closely related, developmental pathways culminating in the musicality and linguistic competence of children. Over the course of the second 6 months of life, this process of divergence first begins, leading on the one hand to the complex phonological structures and stable semantics of language, and on the other to the complex tonal structures of music. Music and language appear to emerge from the same basic emotional framework.

Crying from an Evolutionary Perspective

From an evolutionary perspective, there is a further supportive argument for a potential link between crying and language provided by Dean Falk (2009). She assumes that the persistent adult-directed crying of human infants and the typical infant-directed speech of human mothers are complementary behaviors that represent prelinguistic substrates that paved the way for the eventual emergence of protolanguage.

Mother–child interaction, in which mental states, feelings, and needs are to a large degree vocally communicated, perhaps provided a motor for the evolution of spoken language in the prehistoric development of humankind. With the appearance of physiologically 'premature' birth among our hominid ancestors, in the context of the evolution of upright posture and concomitant skeletal changes affecting the maternal pelvis, hominid babies lost the ability to cling independently to their mothers' bodies (cf Falk, 2009). Temporary separation from and insufficient physical contact with the body of its mother very likely provoked protest on the part of the child. According to the anthropologist Dean Falk (Falk, 2009), the special, very melodic form of vocal communication that exists between a mother and her infant (*motherese*) could well have co-evolved in this prehistoric time. Falk hypothesizes that in the appearance of early forms of *motherese* the decisive step was made toward the evolution of spoken language ('putting the baby down' theory).

All human neonates cry during their first months of life. Nonhuman primate infants may also show a similar behavior. They will respond with 'fussing' ('hoo' vocalizations and whimpers) and crying (or screaming) upon separation from their mother, or upon the perception of physical discomfort and pain. Chimpanzee infants may exhibit, even for extended periods, distress vocalizations from birth that are accompanied by typical facial expressions, where different patterns of vocal-facial expressions are indicative of different degrees of distress (Bard, 2000). However, there is a decisive difference: while human mothers exhibit a variety of behavioral responses to their infants' crying, such as picking up the infant, rocking the infact gently and rhythmically, or nursing, they will also respond vocally by talking or singing to the neonate. A chimpanzee mother never responds in this way (cf Falk, 2009). This makes of human infants and their early vocalizations particularly suitable candidates for future research on the evolution of spoken language.

Neonatal Imitation

Giannis Kugiumutzakis, University of Crete, Crete, Greece

Abstract

Imitation is essential for cultural learning, language and conventional reasoning, but its development been controversial for millennia, and remains problematic. Many psychologists deny newborns imitate, believing that months of learning will need a self-awareness to construct representations of mental states for perceiving others' intentions and emotions. Nevertheless, microanalysis of naturally motivated engagements has proved (1) that a newborn moves with an integrated and emotional self-awareness by proprioception, and (2) can imitate face expressions, vocalizations, and gestures made by another person. Neonatal imitation displays innate alteroceptive readiness for interpersonal dialogic awareness, which is regulated by relational emotions of interest and pleasure.

The Nature of Human Intelligence at Birth

Movements of newborn infants are complex, coordinated, and characteristically human in the adaptations of the whole body for acquiring experience of the outside world with many senses (Trevarthen, 1986). Their movements are emotionally regulated and expectant for sympathetic engagement with the rhythmic expressions of motives and feelings of other persons who offer intimate communication (Trevarthen, 1979). These are adaptations for intelligent life in a human community. They are prepared for in prenatal development of the anatomy of a human body and brain (Trevarthen, 2001), and are made evident by the sensitively directed actions and emotional expressions of the fetus (Trevarthen and Delafield-Butt, 2013). Knowledge of the spontaneous behaviors, narrative awareness, and affective sensibilities of young infants, of their response to the desires and interests aroused in a loving parent, and of age-related developments in communication before language, gives us a natural science of cultural learning, social collaboration and mental health in human families and communities, and of the functions of language.

A Controversial Topic in Philosophy and Psychology

A newborn human body is very immature and its brain, though distinctly human, is small. Many life sustaining functions must change to make use of the new environment outside the mother's body (Nagy, 2011). For many months the infant's life and its changes will depend on maternal attention, support, and care. Nevertheless, the newborn has an ingenious *motor intelligence* and may show adventurous animation with finely coordinated and purposeful actions that direct senses in selective, intentional ways. Within minutes of an easy birth, while accepting gentle and affectionate responses in intimate contact, a baby may gaze with intense interest at the other human being, making delicate hand gestures and sharing smiles or small vocal sounds, sometimes by direct imitation (Maratos, 1973; Meltzoff and Moore, 1977; Kugiumutzakis, 1998, 1999; Butterworth, 1999; Nagy and Molnár, 2004; Reddy, 2008). Postures, gestures, face expressions, and the voice sounds are expectant of sharing experience and emotion in human company. The emotional exchange of parent and child is one of an instinctive reciprocal, playful 'sympathy' with complementary and constructive feelings, not the one-sided pickup of feeling now being identified as 'empathy' (Reddy and Trevarthen, 2004; Kugiumutzakis et al., 2005).

And yet, the oldest records we have of the views of philosophers and physicians deny that an infant can have either self-consciousness or awareness of another person. Respect for the importance of education in fact-based explanation and in the conventions of language, and for the need to cultivate conventions of ethical social behavior, leads infants to be thought of as nonpersons who require instruction to be engaged with other persons' motives and emotions. Medical science has represented infants as delicate organisms needing nourishment and protection, with therapeutic treatment of disorders and capable only of reflex responses. Conscious awareness of self and of others and their purposes, ideas, and feelings are perceived to require weeks, months, or years of learning. Any communication of awareness will wait until the child learns representations of other persons and their actions, and these concepts will be absent or rudimentary until the child can speak and reflect with words on what others' actions mean.

How imitation develops persists as a problem in modern developmental psychology (Reddy and Trevarthen, 2004; Reddy, 2008; Nagy, 2011). Many who experiment with how infants respond to stimuli or master use of objects have denied neonates can imitate on the grounds that appreciation of others' intentions and feelings requires months of learning to construct a basic self-world awareness – how to move as one agent guided by acquired conceptions of objects gained with 'pleasure in mastery' (Piaget, 1962). Once a coherent sense of being in an objective time and space is built, then the actions of others, and their feelings, can be appreciated and adopted as a consciousness of their mental states, or a 'theory of mind.'

The Developmental Psychobiology of the Infant Social Mind

From analysis of detailed recordings of newborns' behaviors in appropriately responsive company that accepts their initiatives and expectations, and with new evidence on how body, brain, and behavior develop before birth, it is evident that a child achieves rational and representational intelligence of a culture and its language on the foundation of innate powers of

self-creation (Trevarthen and Delafield-Butt, 2013). Intentions to move with feeling of the body, and cognitive appreciation of the consequences of being in touch with objects, are regulated from the start by emotions adapted to appreciate the risks of acting in that world (Trevarthen, 2001). The sensitive actions of the fetus are adapted for social cooperation and learning with other persons (Piontelli, 2010).

There is proof that, after a premature birth, smiles, vocalizations and gestures can be ready for engagement with the feelings of life in another person 2 months before term (Trevarthen and Delafield-Butt, 2013). We gain further evidence from the development of affective communication through infancy, regulated by age-related changes in motives for cooperation in play and for sharing practical use of objects (Trevarthen, 1977, in Bråten, 1998).

That neonatal imitation is real and necessary for attachment in parental care and for development of human social and cultural intelligence is supported by advances in the neuroscience of intentions and emotions (Ammaniti and Gallese, 2014). Detailed descriptions of how a young infant can take initiative in communication with parents have transformed the management of perinatal medical care of infants and their mothers (Brazelton, 1979), and analysis of the dynamics of play with infant's motives are leading to new ways of conceiving early education for the development of cultural skills and language, and psychotherapy.

In spite of these advances, it remains difficult for scientific psychology, with its rational bias, to accept that a newborn has sufficient awareness to imitate another person's expressive movements. This disbelief has a long history.

The History of Thinking about Newborn Awareness and Communication

The Ancient Dispute about Neonatal 'Mimesis'

According to Plato and Aristotle, mimesis is an innate human ability, but neonates cannot imitate. They are in a state of 'initial adualism' (Kugiumutzakis, 1998). The Platonic embryo has the inborn 'wisdom' of life, but forgets at birth the essential awareness of its nature, including the sense of *sameness* and *difference* in experience. In a chaotic state, the neonate cannot recognize the other or imitate. Aristotle declared that at birth we are unable to distinguish the self from the other. Because the baby lacks memory and cannot discriminate similarities and differences, it has no positive emotions to express to a parent. "… parents love their children as soon as these are born, but children love their parents only after time has elapsed and they have acquired understanding or the power of discrimination by the senses" (Aristotle, *The Nicomachean Ethics*, 1161b).

Two hundred years after Plato and Aristotle, in the second century AD, the Stoics taught that human newborns posses one of the three innate impulses of affection, called *oikeiosis* or 'familiarity of being' – an affinity for being an organism, an innate orientation to self-love and self-preservation, and thus self-perception. Hierocles was the first to oppose the Aristotelian view with a thesis of innate *dualism* or self–other awareness, for humans and for other animals. "'The first thing that animals perceive is their own parts … both that they have them and for what purpose they have them, and we ourselves perceive our eyes and our ears and the rest. So whenever we want to see something, we strain our eyes, but not our ears, toward the visible object … Therefore the first proof of every animal's perceiving itself is its consciousness of its parts and the functions for which they were given" (Hierocles, quoted by Long and Sedley, 1987, *The Hellinistic Philosophers*, vol. 1, p. 347).

Hierocles' observations were ignored by science for 2000 years. Ideas of initial adualism prevailed in Developmental Psychology until the last quarter of the twentieth century, with notable exceptions among philosophers of the Scottish Enlightenment, Frances Hutcheson, David Hume, Adam Smith, and Thomas Reid, who believed we relate by 'innate sympathy.' Charles Darwin, James Mark Baldwin, Martin Buber and John Macmurray also rejected Cartesian Dualism and opened the way to a new interest in innate relational awareness, now supported by both psychological studies of infants (Reddy, 2008: Stern, 2010), and research on the brain mechanisms of self-regulation and other-awareness (Nagy, 2011; Ammaniti and Gallese, 2014).

Fathers' Diaries of Infants' Early Life

Since the seventeenth century there have been many attempts to make natural descriptions of early human behavior and its embodiment in imaginative moving. These lead to ideas opposing the rational dualism of René Descartes. In particular, there are attempts to understand the nature of immediate interpersonal awareness, about which Descartes had less to say.

In 1787, in his diary of his infant's development Dietrich Tiedemann concludes that the desire to communicate with others 'is rooted in human nature.' Charles Darwin, observing his firstborn son, William, felt that the infant's awareness of others during the first few months is limited, before the emergence of 'practical reasoning or rational, intentional action.' In 1877, he reported that his son, "… had no distinct evidence of his distinguishing and recognising anyone, until he was nearly four months old." Darwin suggested that, "The imitation by articulate sounds of musical cries might have given rise to words expressive of various complex emotions" (On the evolution of language from imitation of expressive vocalizations see Malloch and Trevarthen, 2009).

Tiedemann and Darwin attributed their son's *neonatal* behavior to reflexes. For Tiedemann, while an initial dualism is necessary for the development of intelligent imitation, neonatal imitation of emotional expressions such as the smile may be a primary, sympathetic response. "And herein lies the first source of sympathy; for by looking upon others, who are stirred by some emotion, the soul projects itself into the same situation, wherein it has once experienced that feeling" (Tiedemann, 1787: p. 17, quoted in Butterworth, 1999: p. 73). This was the understanding of Frances Hutcheson and his students, Hume, Smith, and Reid.

William Thierry Preyer observed his infant son with special knowledge of early brain development. He, like Tiedemann, recorded imitation of the mother's smile 1 month after birth. Preyer did not consider this to be 'real' imitation. He believed that the loose organic connection of the spinal cord and the brain in early infancy leads to two 'egos absolutely isolated from each other.' The ego of the spinal marrow (that only feels) is different from the ego of the brain (that feels, sees, hears, tastes,

smells, and speaks). Each one of the imperfectly developed, uncoordinated senses has its separate ego – each sense 'perceives for itself.' Later on their coordination, representations, and concepts (the 'I'-makers) will lead to the formation of the abstract, 'corporate I.' This synthesis is reached *late in the second year*, after many 'playful experimentations' with the infant's own body, with other persons and with objects.

Modern Developmental Psychology: From Unconscious Emotionality and Schemas for Objects to Innate Intersubjectivity

James Mark Baldwin (1897) developed a comprehensive theory of the cognitive and social development of organisms, which has informed subsequent research on the genesis of infant self and its intelligence. However, the richness of Baldwin's understanding of the generative powers of organismic action with awareness, also considered of basic importance to psychology by William James and James Herbert Mead, was dismissed in the United States with the advent of behaviorism and learning theory, which dominated teaching and research on 'psychological mechanisms' for five decades after James Watson defined its method in 1913.

Baldwin recorded the development of social reactions in four infants, including his two daughters. He accepted repetition of actions as essential to the development of intelligence in the brain, and his developmental theory assumed that to be social a person must be imitative. His explanation of imitation is based on his theory of 'circular reactions,' the performance of stimulus-repeating movements, found in ontogeny, phylogeny, and heredity. A stimulus triggers a motor process that tends to reproduce itself and the same sensory feedback, generating repeating psychological sequences of 'reality, image, movement.'

According to Baldwin, all organic selection tests its awareness, retaining the vitally good and pleasurable relations with the environment and suppressing bad and unpleasant stimulation. It is called 'circular' because its action tends to repeat itself to reproduce stimulation *caused by movement*. It is 'conservative,' since it keeps up old movements, creating habits, but it is also 'playful,' open to new adaptations by the overproduction of movement variations. Play permits change by selection. Both evolution and development require cooperation between the organism and the environment. A way of life is selected, by 'intelligent adaptation.' The theory resembles that of the creative relation of an organism to its 'life world' presented by Jacob von Uexküll (1957), which inspired the development of the theory of animal semiotics or social signaling of Thomas Sebeok and the ethologists.

Baldwin proposes that the only way a new movement can arise with purpose is playfully, by making the movements already possible so excessively and with so many varieties of combination that new, useful, and pleasurable adaptations may occur. Circular reactions or organic imitations appear at birth and they grow by distinguishing and selecting pleasant, useful self-imitations, and, eventually, become heteroimitations of other's actions. Unlike other species, infants' imitations are not limited by fully functional instincts. For humans, experimental imitation, play, is the main instrument of learning and leads to the acquisition of functions from the social environment.

Baldwin assumes that for the neonate, the self, other persons, and inanimate things are experienced as *objects*. The deliberate movements of other persons begin to attract attention and acquire meaning during the first 6 months. After 6 months, with new cerebral development there appears *persistent imitation* of others' actions, which makes the baby feel, *like them*. By imitating them, the infant acquires the 'germ of his *sense of agency*' and starts to discriminate the 'characters' of the others.

Psychoanalytic Theory of Neonatal Identification with the Vital Impulses of the Other

In his works on primary identification, Sigmund Freud proposes that identification is "… the earliest … the original expression of an emotional tie with another person …" (1921: pp. 134, 137, 140), but in his writing about shared feeling of the Id he makes no reference to imitation. With most psychoanalysts who followed him, Freud accepts the concept of initial adualism of Baldwin. Before the emergence of the ego, food intake and sexual activity are undifferentiated as a source of organic pleasure, and the neonate and the young infant is unable to discriminate his bodily self from the mother as source of comfort and pleasure. Exactly when, during the oral stage of primary narcissism or autoerotism and primary identification with the mother, imitation appears, is not clear in the writings of Freud.

Later the psychoanalysts Fenichel and Gaddini proposed that a primitive imitation is possible from the start. These early imitations are involuntary, reflexlike, emotional, immediate reactions, obeying the pleasure principle, and felt as 'undifferentiated wholes.' Gaddini argued that, during the adualisic, narcissistic period, imitation is a core factor in early development of the ego and adaptation. Early, 'realistic' identification presupposes early imitation, which is concerned 'only with unconscious fantasy' in the absence of the gratifying objects.

In Psychoanalysis, any acceptance of the idea of the neonatal imitation came late. Early infant imitation was conceived as an involuntary, unconscious, adualistic experience regulated by primary emotional systems of the Id. The neuropsychoanalitic theory of primal or lower brain emotional consciousness presented by Jaak Panksepp (2009) is compatible with many elements of Freud's theory of unconscious emotions.

The psychoanalyst and developmental psychologist Daniel Stern, integrating findings on infant communication of the preceding 30 years, in *The Interpersonal World of the Infant* first published in 1985, challenged the traditional account of the original state of the infant's psyche, and of the stages of ego development. He proposed that the human infants: "… never experience a period of total self/other undifferentiation. There is no confusion between self and other in the beginning or at any point during infancy … There is no symbiotic-like phase … The period of life from roughly nine to eighteen months is not primary devoted to the developmental tasks of independence … It is equally devoted to the seeking and creating of intersubjective union with another" (Stern, 2000: p. 10). Stern recognized that "In light of the new evidence on other-centered-participation shown by infants in their many forms of imitation, as well as the new findings on mirror neurons

and adaptive oscillators, I am now convinced that early forms of intersubjectivity exist from almost the beginning of life" (Stern, 2000: p. xxii). Stern describes a layered model of development in which the first phase of intersubjective awareness, and all subsequent phases of its elaboration, remain as foundations throughout life, and can be invoked in the therapeutic process with adult patients (Stern, 2000: Revised Figure 2.2, p. xxv).

Piaget's Rejection of Neonatal Imitation

For Piaget (1962), who by his tests of the construction of object-conceiving abilities of infants, laid the foundation for developmental cognitive psychology, the neonate cannot imitate. While there is an innate tendency to imitate, the 'technique' of imitation must be learned or practiced. The innate element is termed *reproductive* or *functional* assimilation, a mechanism that motivates *self-repetition* of a sensory motor schema, recalling Baldwin's 'circular reaction.' This develops by integration of new 'external elements' i.e., acquired, tested, and confirmed experiences, which become schemas for useful objects (Piaget, 1962: p. 5).

With Baldwin, Piaget assumes that *self-imitation precedes and leads to heteroimitation*, that imitation has to be, at first, an *intrapersonal phenomenon*, which gradually becomes *interpersonal* in infancy, then at 2 years of age becomes again intrapersonal as interiorized imitation or thinking about it, as in the contemporary 'theory of mind.' In his words:

> Our study of the beginnings of representation in the child will mainly be in those fields where the individual processes of mental life dominate the collective factors, and we shall emphasize these individual processes particularly in the case of imitation, which though it leads to inter-individual relationships does not necessarily result from them.
>
> 1962: p. 2

For Piaget, imitation during the first 8 months of life is a circular reaction because the infant experiences the actions modeled by another person as a continuation of self-related activity. 'True,' spontaneous imitation, based upon active, spontaneous assimilation appears later in development and lasts. Early 'pseudoimitation' of a facial model does not last, says Piaget, except under the influence of continual stimulation. After the eighth month, Piaget invokes the passive process of *association* for the further development of imitation, because the active processes of *assimilation* and *accommodation* cannot explain the appearance of facial imitation. In other words, he disregards intracorporal proprioceptive sensibility, which the physiologist Charles Sherrington discovered and called 'the felt Me.' Piaget, echoing the ideas of Preyer, notes that "training in imitation is necessary, especially when it is a case of imitation of movements which the child cannot see himself make" (1962: p. 41). The newborn infant, 'amid the chaos of impressions by which he is beset' (Piaget, 1962: p. 83) during the first 30 days, does nothing more than exercise his 'pure' reflexes – exercise which, after the first month, will lead gradually to imitation.

The Role of Emotions in Early Imitation: The Love of Shared Knowledge

The ancient Greeks believed mimesis could not occur between emotionless persons. Over the last 100 years, the emotional or 'sympathetic' aspect of early mimesis has been accepted by some developmentalists, notably Baldwin, Freud, Guillaume, and Wallon, but the hypothesis of a strong link between emotion and imitation was subsequently dismissed under the influence of Piaget's rational philosophy (Kugiumutzakis, 1998: pp. 81–88; Kugiumutzakis et al., 2005: pp. 161–163).

Piaget made only four observations of his newborn infant between the first and the sixth days after birth, 1% of his corpus of observations on infant imitation. The infant was asleep, drowsy or crying, states of self-expression that disfavor imitation, and he only tested for imitation of crying (Piaget, 1962: pp. 7–8). He gives equal status to cognitive and emotional aspects of action, assuming that the cognitive provides structure, and the emotional the 'energetic force' of behavior, stressing that in imitation the emotion of 'interest' has a purely cognitive origin.

Piaget's views on the 'emotional' aspect express his radical cognitivism. His observations of infants' curiosity and object concepts cannot explain the sympathetic companionship of artful, humorous play and cultural learning, or the primary sympathetic self–other awareness that enables a newborn infant and a parent to enjoy their affection by reciprocal imitation.

Recent Research on Neonatal Imitation

The theory that imitation of another person's face expression is impossible for a newborn was shown incorrect by Zazzo in 1957, and disproved experimentally by Olga Maratos in her PhD thesis presented to Piaget in Geneva in 1973, and later by tests made independently by Meltzoff, Kugiumutzakis, Vinter, Field, Reissland, Heimann, and Nagy, all of whom used microanalysis of film or television recordings to record the infants efforts. Maratos's work, which included consideration of prenatal motor coordination, persuaded Piaget, who had rejected Zazzo's work, to change his mind and say, 'Indeed they imitate' (see Reddy, 2008: p. 46).

It is important to remember that conscious anticipation of the stimulations that arise with any organized movements within one's own body depends on the regulated rhythm of movements (Trevarthen, 1986). Live communication requires coregulation of the timing and dynamic modulations in movements between subjects (Stern, 2010). Condon and Sander, studying 'self-synchrony' of movements of body parts in infants and adults, published evidence in 1974 of 'inter-synchrony' of neonates climaxes of arm movement with speech of the mother, suggesting that the infant's impulses to move is 'entrained' by the mother's behavior. Trevarthen interpreted films of mother–infant communication as revealing 'mutual regulation,' "infant and mother appear to achieve a more complex co-operation which only occasionally results in synchrony of individual acts when mother and infant overlap to the same beat. Usually their acts alternate or complement one another" (Trevarthen, 1977: p. 241). This implies shared circular sensory motor reactions that test both self- and interregulations of

movement in experimental 'playful' ways, through periods of time that are shared with prospective control, as in music (Malloch and Trevarthen, 2009).

Meltzoff and Moore (1977) confirmed Maratos's findings, demonstrating that newborns aged 2 to 3 weeks can imitate tongue and lip protrusion, mouth opening, and finger movements. In cross-sectional and longitudinal studies with newborns and older infants, Meltzoff and collaborators added new findings on the development of vowel imitation between 3 and 5 months, on deferred imitation, and on the ability of infants at 18 months to infer goals from people's unsuccessful attempts to manipulate objects. Meltzoff and Moore's claims generated intense debates. Failures to replicate the findings, using strict controls of stimulation insensitive to the infant's initiative, supported convictions that the movement was a primitive reflex controlled by an 'innate releasing mechanism,' an 'arousal' response to the stimulus, or a product of associative learning of contingent acts (see Heimann in Bråten, 1998).

Meltzoff hypothesized that newborn facial imitation involves an 'active intermodal mapping' (AIM mechanism). "Infants' self-produced movements provide proprioceptive feedback that can be compared to the representation of the observed act by vision. AIM proposes that such comparison is possible because the observation and execution of human acts are coded within a common framework. We call it a 'supramodal act space'" (Meltzoff, 2002: p. 24). This is offered as the foundation of the 'theory of mind' proposed by Baron-Cohen to explain joint attention to purposes of object use developed at the end of the first year. Trevarthen (1977) showed evidence that acts directed with 'prospective control' from birth, by hands or by head and eyes to objects seen or heard outside the body, are coordinated in a single integrated 'behavior space' defined by the prenatal mapping of body form, sensory fields and movement space in integrated neuronal nets of the brain (Trevarthen, 2001). This innate intentional subjectivity is the foundation for neonatal intersubjectivity or communication of intentions (Trevarthen, 1979).

There has been much discussion about whether newborns have 'feelings of emotion' and a capacity to imitate their expression. Tiffany Field and colleagues showed that newborns can imitate an actor's expressions of happiness, surprise, and sadness, and they studied changes in attentiveness and imitation of infants from 2 to 6 months of age (Field et al., 1982). Imitation of other infants' crying, called 'contageous' has been interpreted as an automatic response 'confusing' self-stimulation with stimulation from another. Close observation of expressions of the face while newborns imitate a variety of expressions of different parts of the body supports the theory that they feel emotions of interest and pleasure in the 'intersubjective, imitative game' (Kugiumutzakis, 1998: p. 78; **Figure 1**).

Jacqueline Nadel and collaborators have demonstrated that a newborn infant can imitate two-dimensional images of tongue protrusion from a mouth seen on a screen, or the movements of a robot protruding a tongue (Nadel, 2014). The infants move with effort, selectively attending to and matching the artificial visual image of part of a human being to their own mouth moving. The dynamics of the images must be important, but clearly the infant has, within the first few days, a capacity to focus attention on an isolated feature of the face, and identify it with their own corresponding organ. The infant brain has 'feature detectors' for eyes, mouth, and tongue. Dynamic configurations of a smile or scowl on the whole face can also be detected as signals of different emotions.

Figure 1 A cycle of imitations of mouth opening with a female infant 20 min after birth. Recorded in a maternity hospital in Herakleion, Crete in 1983 by Giannis Kugiumutzakis for his PhD research at the University of Uppsala. (a) (0 s) The researcher presents a wide open mouth for the first time to the attentive infant, focusing on his mouth, and with slightly closed eyes and pursed mouth. (b) (+6.3 s) The researcher opens his mouth for the fourth time. The neonate continues to observe his mouth with evident interest. The right hand moves up. (c) (+0.8 s) The researcher opens his mouth for the fifth time. The neonate imitates him once, synchronously while watching his mouth. The right hand closes. (d) (+1.8 s) The infant imitates a second time, looking up at the researcher's eyes as he waits. (e) (+1.8 s) Both pause, waiting. The infant is still looking at his eyes. (f) (+0.6 s) The infant makes a third large imitation while looking at the researcher's mouth.

Using a combination of naturalistic or spontaneously timed interactions and experimental or controlled methods of observation, Kugiumutzakis examined imitation by studying 170 infants within 10–45 min after full term or preterm births, most natural but some by Caesarian section. He presented tongue protrusion and mouth opening, blinking of his eyes, and three sounds, /a/, /m/, and /ang/ to alert infants (**Figure 1**). His findings are based on what he experienced in engagement with the infants while presenting the models, and on analysis of the videos. Some responses were also acts in spontaneous behavior of the infants, but these were produced significantly more often in the presence of the model. All the models of face movements seen were imitated by full terms or preterms, regardless of the method of birth. No differences were found between male and female infants. The babies tried to imitate the sound /a/, with mouth opening and occasional sounds, but they did not try to imitate the sounds, /m/ and /ang/.

Most neonates made a visible effort to direct their attention, first by staring, then by visual exploration directed to the moving part of the experimenter's face, or to the open mouth a sound. The baby attended with *frowning, a movement that* Darwin said shows the mind to be 'intent on one object' (Darwin, 1938 Notebook, cited in Gruber, 1974: p. 341). The periods of visual exploration and frowning of premature neonates were longer than those of the full-term infants. During the presentation of the sound a model, the majority of the imitators turned their heads to localize the sound, with eye widening while the brows were held high, a sign of attentive listening. A few full-term neonates glanced at a face movement briefly, then reproduced the model in 3 or 4 s. Some responded immediately after the first or the second presentation of the /a/ sound. Those that imitated the blinking model, attended more slowly (range 8–19 s) than the imitations of tongue protrusion and mouth opening.

None of these behaviors are automatic reflexes or fixed action patterns. Sometimes the neonates reproduce the models once, matching the model's action accurately. The majority of imitations of the eye-movement were of this kind. More often, with tongue protrusion and mouth opening, the model movement was repeated several times as a series of attempts becoming progressively more accurate, sometimes beginning with exploratory movements of the tongue inside the buccal cavity. This confirms observations of Maratos (1973) and Meltzoff and Moore (1977) that the infants 'try' to improve their imitations.

In some cases, the first imitative effort was a clear reproduction of the model, with additional 'efforts' becoming less accurate as if interest was lost. Tongue protrusion was imitated more easily than mouth opening, and they imitated these oral models more frequently than the eye blinking, which evoked awkward movements of the eyelids. Imitative responses to the sound /a/ were strained, usually by an intense explosion of a prolonged and unstructured /a/ sound accompanied by stretching hand movements and closed eyes. A considerable number of cases failed to imitate, again indicating that the responses are not simple reflexes.

A major advance in experimentation with the motives and emotions of neonates for communication was made by a Hungarian medical doctor and psychologist Emese Nagy who, in her PhD research with Peter Molnár in a hospital in Szeged, offered a receptive interpersonal approach in tests that proved the infants imitated to take part in a dialogue (Nagy and Molnár, 2004). She obtained imitation of an index finger extension, then paused looking at the infant. Newborns, while waiting for the experimenter's response, spontaneously produced the previously imitated gesture, initiating a 'provocation.' Measurements of heart beats revealed that the effort of imitation was accompanied by heart rate increase, a sign of excitement, while presentation of a gesture as provocation was accompanied by heart rate deceleration, indicative of attention. Infants are not only capable of imitating a model gesture, but can also invite an imitative response, thus sustaining an emotionally charged interaction. These findings constitute a laboratory demonstration of the first dialogue (Nagy, 2006, 2011), and they show how human 'imprinting' or affectionate attachment begins. Neonatal imitation is a precursor of the active intersubjective regulation of protoconversations with alert infants in the second month (Trevarthen, 1977, 1979, 1986; Malloch and Trevarthen, 2009).

The Key Features of Neonatal Imitation

Not all newborns imitate. Imitation is favored by an alert awake state with comfortable posture and sensitive engagement with the other person. Repeated stimulations in experimental tests of imitation of intended signs may inhibit the infant's readiness to 'play the game of imitation.' Premature infants have difficulty regulating their state of attention and body coordination, and their immaturity restricts their capacity to imitate. The actions that are imitated may also be performed spontaneously by the newborn, with no incentive from a 'model.' The important fact is that such actions expressive of the infant's motive state may be significantly increased and developed through imitative exchange in 'felt immediacy' (Bråten, 2009).

Some actions, such as mouth opening, tongue protrusion, hand movement, are imitated often and quickly, sometimes accurately in the first performance. Others, including eye closing, simple back vowels, different finger extensions, are less frequent and often slower with progressive improvement of accuracy of reproduction; more complex vocalizations requiring control of movements of the front of the mouth and tongue are not imitated.

Imitations are accompanied by movements indicative of effort and concentration. General body activity, staring, frowning, grimacing, emotional expressions of focused 'interest' and 'pleasure,' and complex hand gestures, precede and accompany imitations (**Figure 1**). Infants search for reactions to their communicative expressions, and this leads to repetition of imitated acts as 'provocations' for the other to imitate. Nagy's measures of heart beat show that neonates are physiologically aroused by emotions, when they are sharing imitations as purposeful expressions that appreciate response – imitation being preceded by heart rate acceleration, and provocation by heart deceleration.

Finally, in all natural, attentive and sympathetic engagements of expressive movements with alert newborn infants there is *reciprocal imitation* in *rhythmically patterned interchange*. Parents happily imitate too, and do so *more than the infants*.

These behaviors, timed to achieve intersynchrony between intentions and experiences, are necessary for the development of cooperative involvement of purposes with objects and their affective appraisal, for constructive projects, and for creating conventional narratives in art and with symbols. They are adapted for cultural learning by 'intent participation' in *sympathetic shared action and experience*.

Neurobiology of Neonatal Imitation or 'Primary Dialogue'

The brain mechanisms for self-awareness in body movement and body form are, with the corresponding peripheral sensory motor organs, formed for shared self–other awareness before birth (Trevarthen, 2001), when the embryo and fetus are in intense physiological contact with the mother's body and in 'amphoteronomic' or shared autonomic regulation (Trevarthen et al., 2006). Different motor and sensory capacities form at different stages of development. The first sensations of movement are by within-body proprioception and by self-touching of the hands and with the face and mouth (Piontelli, 2010; Trevarthen and Delafield-Butt, 2013). Discriminating awareness of another individual is first by taste and touch, then, in the last trimester by hearing. Sight is functional before term and may contribute to both self-awareness and other-awareness within minutes of birth. The sensory motor systems for self-regulation, of eyes, face, voice and hands, are adapted for transformation to serve dialogic or synrhythmic self–other regulation from birth (Trevarthen et al., 2006; Nagy, 2011). The movements most readily imitated, notably round the mouth, are those with larger representation in the newborn brain and with better developed muscular and sensory systems.

The intermodal matching between proprioception of a face movement of the self and vision of that movement in another person, the AIM hypothesis, is necessary but not sufficient to explain imitation, which depends on matching organized intentional motor systems that seek confirmation by different forms of reafference. Motor impulses are regulated in time by a hierarchy of rhythms generated in the brain and body (Malloch and Trevarthen, 2009), by parameters of active proprioception and exproprioception leads to 'alteroception' or awareness of the motives and expectations of another individual in 'felt immediacy' (Bråten, 2009).

An intention generates anticipation of correctly timed sensory feedback as 'experience.' In dialogue, the form of the movement displays this intention and leads apprehension of the experience of the other in 'synrhythmia' (Trevarthen et al., 2006), which includes both synchrony and concordant alternation or shared serial ordering of intentions, with affective appraisal. This results in the two-way communication of 'sympathy,' which must be an interchange of complementary affective states, not the unilateral understanding of 'empathy' (Reddy and Trevarthen, 2004).

Conclusion

Our abstract notes that, "imitation is essential for cultural learning, language and conventional reasoning, but its development been controversial for millennia, and remains problematic …" If attention is restricted to the artificial products of human collaboration and invention, to cultural history, the biological process of development that generates shared experience is ignored. Evidence we have reviewed indicates all that cultural intelligence achieves, and the well-being of individuals in human relationships, depend upon the environment-expectant motor intelligence we are born with, and the ability and infant has to sense, respond to, and share the motives and feelings implicit in the movements of another person. This ability is impulsive within the bodies and minds of infant and adult, with the matching rhythms and sympathetic affective regulations. They join in the hypermotility and 'vitality dynamics' of human actions, with story making imagination of 'communicative musicality,' a combination of gestural and vocal semantics, of dance and song (Malloch and Trevarthen, 2009; Stern, 2010).

A neonate's imitation of an expression offered by another person with attention for response, establishes a first cooperative enterprise in shared awareness of life. With no interest in technical artifacts or symbols, and limited by the infant's immaturity and lack of world knowledge, it confirms intimate engagement with a person who is present in the infant's awareness as company. This individual may have articulate assumptions or beliefs that preclude acceptance of the infant's movements as acts motivated for communication – a philosopher or medical doctor may believe the infant has a sensitive body but no mind; a psychologist may look only for signs of physiological arousal.

The infant's imitation may, however, be more warmly accepted with intuitive affection – as a request for milk by a mother wanting to breast feed, as a sign of interest in telling her something by a proud grandmother, as a joke by a sibling seeking a playmate. It becomes a two-way mental event, an act of primary intersubjectivity expecting confirmation – not a sensory motor circular reaction within the body of the Self, but one coupled to another's awareness of Self in an intersubjective loop of 'vitality dynamics' with emotional 'attunement' (Stern, 2000).

From the start, imitation supports collaborative adventures in moving, even though it has limited scope for imagination of goals or objects for action. The infant's mimesis is playful, motivated by interest and pleasure in sharing (Turner, 1982; Donald, 2001). It is made not just to be a single act of shared 'like me' experience, but becomes part of a 'story' or 'plot' that 'grows meaning' over tens of seconds in mutually sustained expectation of a rhythmic project of communication, engaging two persons in a nonverbal 'narrative' (**Figure 1**). Neonatal imitation is both 'autopoetic' and innately dialogical, self-making activity of a human being who has need for company – a biological capacity for the growth of a sociable 'consensuality' upon which all cultural understanding and all languages of human communities depend (Maturana and Varela, 1987). It is 'heteropoetic,' originating from a mind seeking, cocreating, and sharing an intersubjective imitative game adapted to make relationships in a community.

Most reports of neonatal imitation have been made with Caucasian infants in Europe or the United States, in technical and rational European cultures, which value intelligence that is guided by laws of behavior to promote practical and social conformity among autonomous individual minds, rather than the intuitive prosocial life of community (Bierhoff, 2002).

Kugiumutzakis (1985) in his research in Crete observed facial imitation by two black Afro-American infants in the first day after birth – a 1-month premature neonate, and a baby born full term. A study made by Reissland (1988) in the Himalayas of Nepal, with Indo-Aryan infants of Maithil parentage who imitated lip movements of the author within the first hour after birth, confirms that the infant's motives and the adult human response to them transcend differences in race, and also in beliefs about the nature of human intelligence and traditional rules of life to sustain acquired rituals of technical creativity and social responsibility.

Neonatal Social Isolation: Effects on Neural Function

Takuya Takahashi, Graduate School of Medicine, Yokohama City University, Yokohama, Japan; and Albert Einstein College of Medicine, Bronx, NY, USA

Abstract

Neonatal stressful environment could influence the establishment of neuronal circuit formation and result in the various psychiatric disorders such as depression, anxiety disorders, and personality disorders. Despite their fundamental importance, the molecular and cellular mechanisms underlying how neonatal stress affects nervous system remain poorly understood. Here I review about how neonatal social isolation stress, an environment caused by neglect, alters developmental circuit formation in the cortex. Neonatal social isolation disrupts experience-dependent synaptic AMPA receptor delivery in the somatosensory cortex, leading to disturbance in somatosensory functions. These recent findings could shed light on the understanding of social stress-induced mental illness.

Introduction

Neonatal mental stress can have profound effects on the nervous system (*see* Stress in Childhood: Effects on Development). In particular, social isolation early in life, an environment caused by neglect (a form of child abuse), can induce mental stress and lead to various psychiatric disorders such as depression, drug addiction, and borderline personality disorders (Insel and Fernald, 2004; Khonicheva et al., 2006). A number of studies have reported a positive relationship between child maltreatment and personality disorders such as borderline personality disorder, which exhibits prominent deficits in social behaviors (Allen et al., 2013; Bierer et al., 2003; Johnson et al., 2000; Tyrka et al., 2009; Widom et al., 2009) (*see* Borderline (Patient) Personality). Impulsive behaviors and emotional instability are common in borderline personality disorders; depression, aggression, substance or alcohol abuse, eating disorders, indiscriminate sex with multiple partners, quitting jobs or personal relationship, and self-injury (Sadock and Sadock, 1996). Borderline personality disorder affects 1–2% of population (Sadock and Sadock, 1996). Due to the complicated regulation of neuronal functions by stress (Stranahan et al., 2006; Wallace et al., 2009) (*see* Stress in Adolescence: Effects on Development), elucidation of how stress affects the nervous system at the molecular, cellular, and circuit levels is a crucial step toward the effective treatment of stress disorders by neonatal maltreatment.

Early postnatal experience establishes normal functioning cortical circuits (Buonomano and Merzenich, 1998; Fox, 2002). Sensory experience through whiskers, an important tool of social communication in rodents (Ahl, 1986; Strozik and Festing, 1981), leads to a prominent increase in excitatory synaptic transmission in the barrel cortex during first 2 weeks after birth (Takahashi et al., 2003).

Information from a neuron to other neurons is mediated by the structure, called synapse. α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type glutamate receptors mainly mediate excitatory synaptic transmission in the central nervous system (Bredt and Nicoll, 2003; Hollmann and Heinemann, 1994). Upon stimulation of presynaptic neurons, glutamate is released from the presynaptic terminal and binds to glutamate receptors including AMPA receptors. AMPA receptors form ion channels, and binding of glutamate opens channel and induces ion flux. The ion flux through AMPA receptors changes the membrane potentials and conveys information to postsynaptic neurons. The number of synaptic AMPA receptors determines the synaptic responses of postsynaptic neurons and regulates neuronal activity (Barry and Ziff, 2002; Bredt and Nicoll, 2003; Kessels and Malinow, 2009; Malinow and Malenka, 2002; Scannevin and Huganir, 2000). Tetanic synaptic stimulation elevates synaptic responses. This phenomenon is called Long-term potentiation (LTP) and has been suggested to be the cellular basis of neuronal plasticity including learning and memory. LTP-inducing stimuli deliver GluA1-containing AMPA receptors into synapses, increase the number of synaptic AMPA receptors, and elevate synaptic response *in vitro* (Hayashi et al., 2000; Zhu et al., 2000). *In vivo*, whisker experience drives GluA1 (or GluA4)-containing AMPA receptors into synapses and potentiates synaptic responses in the developing barrel cortex, which is a cortical area receiving input from whiskers (Clem and Barth, 2006; Miyazaki et al., 2012a; Takahashi et al., 2003). Synaptic trafficking of GluA1-containing AMPA receptors contributes to behavioral modification in several systems such as hippocampus-dependent learning (Cui et al., 2008; Engblom et al., 2008; Hu et al., 2007; Humeau et al., 2007; Jitsuki et al., 2011; Kessels and Malinow, 2009; Lee et al., 2003; Mitsushima et al., 2011, 2013; Reisel et al., 2002; Rumpel et al., 2005; Tada et al., 2013; Vialou et al., 2010).

Previous studies have shown that stressful environments such as social isolation affect LTP (Kehoe and Bronzino, 1999; Kim and Diamond, 2002). While some stress paradigms attenuate LTP in the hippocampus (Diamond et al., 1994a; Diamond and Park, 2000; Foy et al., 1987; Xu et al., 1997), other protocols, such as brief exposure to a predator, enhance LTP (Hu et al., 2007). Thus, the effect of stress on synaptic plasticity may be dependent on the stress protocol. However, the molecular mechanism of how behavioral stress attenuates synaptic plasticity was still unclear.

Rodents and humans may display similar effects of neonatal maltreatment on the nervous system (Diamond

et al., 1994b; Etherton et al., 2009; McGowan et al., 2009). In this section, we review recent findings that neonatal isolation perturbs experience-driven synaptic AMPA receptor delivery in the rat barrel cortex and discuss about the potential mechanisms of how neonatal maltreatment induces mental disorder in human.

Social Isolation Disrupts Whisker Experience-Dependent Synaptic Delivery of AMPA Receptors

In order to study the effect of social isolation on receptor trafficking, we isolated rat pups from their mother and other siblings for 6 h day^{-1} from postnatal (P)7 to P11 (Zimmerberg et al., 2003). We expressed green fluorescent protein (GFP)-GluA1 in the layer 2/3 of the barrel cortex of either isolated or nonisolated siblings from the same litter at P12 with virus. Recombinant GluA1 forms homomeric receptors which show little outward current at positive potential (while endogenous AMPA receptors display current at both negative and positive potentials) and thus synaptic incorporation of recombinant AMPA receptors is detected as an increased rectification (ratio of response at −60 to +40 mV) of AMPA receptor-mediated synaptic transmission. Litters were maintained in normal condition after viral injection and acute coronal brain slices were prepared at P14. Animals were maintained with whiskers intact throughout the experiment. Whole-cell recordings of layer 2/3 infected pyramidal neurons and nearby noninfected neurons were conducted and evoked synaptic transmission by stimulating layer 4. GFP-GluA1 infected neurons from nonisolated control siblings showed increased rectification compared with nearby noninfected neurons (Miyazaki et al., 2012b). However, no increase of rectification was detected from GFP-GluA1 expressing neurons in isolated animals (Miyazaki et al., 2012b). Therefore, experience-driven synaptic delivery of GluA1 was prevented by social isolation at this early postnatal period. In order to examine if synaptic delivery of endogenous AMPA receptors was attenuated by social isolation, we monitored the ratio of AMPA to *N*-Methyl-D-aspartic acid (NMDA) responses (A/N). If the number of synaptic AMPA receptors is large, A/N ratio is high. In brain slices from P14 animals isolated between P7 and P11 for 6 h day^{-1}, the A/N ratio was significantly lower than that observed in nonisolated animals of the same age, indicating that social isolation from P7 to P11 disrupted synaptic delivery of endogenous AMPA receptors (Miyazaki et al., 2012b). Interestingly, mother separation for 6 h day^{-1} (but several pups were kept together and thus social interaction was maintained) or transient blockade of whisker input for 6 h day^{-1} during P7–P11 did not prevent synaptic AMPA receptor delivery (Miyazaki et al., 2012b). This suggested that isolation-induced prevention of AMPA receptor trafficking is not due to the lack of nutrition from the dam or potential reduction of sensory deprivation by isolation.

Whisker experience drives the delivery of GluA4 but not GluA1 to layer 4–2/3 pyramidal synapses in the barrel cortex during P8–P10, while GluA1 but not GluA4 is delivered to these synapses during P12–P14 (Miyazaki et al., 2012a). Social isolation for 6 h day^{-1} from P4 to P7 disrupted experience-driven synaptic GluA4 delivery during P8–P10 as well as GluA1 trafficking during P12–P14 (Miyazaki et al., 2012b, 2013).

Consistent with these results, social isolation for 6 h day^{-1} either during P4–P7 or P7–P11 prevented LTP induction at P14 (Miyazaki et al., 2012b). This also indicates that social isolation disrupts biochemical pathways necessary for the trafficking of AMPA receptors.

Thus, neonatal social isolation severely affects synaptic maturation throughout early postnatal development.

Glucocorticoid Mediates Social Isolation-Induced Disruption of AMPA Receptor Delivery into Synapses

Corticosterone is a major stress hormone in rodents. Since the active form of corticosterone is free corticosterone (rather than that bound to corticosterone binding globulin), we investigated the free blood corticosterone level. During social isolation, prolonged rise of free blood corticosterone level was observed (Miyazaki et al., 2012b).

In order to test if the rise of corticosterone during social isolation mediates the prevention of AMPA receptor delivery, we injected RU486, an antagonist of glucocorticoid receptor (GR), during 6 h day^{-1} social isolation from P7 to P11. We performed the same electrophysiological assay as described above and found that systemic injection of RU486 blocked the isolation-induced attenuation of experience-driven synaptic GluA1 delivery at layer 4–2/3 pyramidal synapses of the barrel cortex during P12–P14 (Miyazaki et al., 2012b). Application of RU486 also prevented isolation-induced blockade of GluA4 delivery during P8–P10 (Miyazaki et al., 2013). Further, local injection of RU486 into the barrel cortex during social isolation procedure prevents isolation-induced blockade of synaptic AMPA receptor delivery (Miyazaki et al., 2012b). When Glucocorticoid receptor (a receptor of stress glucocorticoid hormone) is activated, it is translocated to the nucleus. Neonatal isolation translocates glucocorticoid receptor into the nucleus of the layer 2/3 neurons of the barrel cortex, suggesting the activation of glucocorticoid signaling in the barrel cortex by neonatal social isolation (Miyazaki et al., 2012b). These indicate that corticosterone mediates isolation effect on synaptic AMPA receptor delivery directly at the barrel cortex. Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII), a crucial kinase for synaptic AMPA receptor delivery (Lisman et al., 2002), is also activated in the barrel cortex during neonatal social isolation in the glucocorticoid activation-dependent fashion (Miyazaki et al., 2012b). Interestingly, injection of propranolol, a blocker of β-adrenergic receptors (noradrenaline is another stress hormone), during social isolation did not prevent isolation-induced blockade of GluA1 delivery, indicating that noradrenaline does not mediate isolation effect on synaptic AMPA receptor delivery (Miyazaki et al., 2012b).

In order to elucidate further, the role of increased glucocorticoid on experience-dependent synaptic delivery of AMPA receptors, we examined if injection of glucocorticoid mimics the effect of social isolation. Animals injected with corticosterone from P7 to P11 were housed in normal environment. This procedure also blocked experience-driven synaptic GluA1 delivery (Miyazaki et al., 2012b). Injection

of corticosterone during P4–P7 also blocked GluA4 delivery (Miyazaki et al., 2013).

These results indicate that elevated glucocorticoid level mediates isolation-induced prevention of experience-driven AMPA receptor trafficking to synapses via the activation of CaMKII.

Whisker–Barrel Function Is Attenuated by Social Isolation

The disruption of synaptic GluA1 and GluA4 delivery in the barrel cortex could result in an attenuation of the sensitivity of each barrel to the corresponding whiskers. To examine this, we measured the sensitivity of individual neurons in response to the deflection of whiskers with *in vivo* tetrode recordings from a single barrel. Whiskers with the highest sensitivity were defined as principal whiskers. First, we measured the response to principal whiskers deflections of rats either with or without social isolation at juvenile age. We found that the response by the deflection of principal whiskers of isolated animals was significantly smaller than those of control animals, indicating that the sensitivity of the barrel to its principal whisker was attenuated (Miyazaki et al., 2012b). This effect of isolation is due to the attenuation of AMPA receptor delivery, since the expression of GluA1 delivery blocking peptide in the layer 2/3 of the developing rat barrel cortex also exhibited the same effect as social isolation (Miyazaki et al., 2012b).

We next examined the effects of the attenuated whisker sensitivity on behavior. We assessed the disruption of whisker sensitivity with the ability of an animal to detect distances using a modified version of the gap-crossing task, which is known to be dependent on the detection ability of whiskers (Barneoud et al., 1991; Hutson and Masterton, 1986). In this task, rats were initially trained to find a reward at the opposite end of a runway. After this training phase, a gap was inserted in the runway and was widened at 0.5 cm intervals. The gap was widened until rats could not step across it. This gap size was defined as the upper threshold (SU). Subsequently, the gap was narrowed at 0.5 cm intervals until rats could cross it. This gap size was defined as the lower threshold (SL). The difference between SU and SL was calculated (defined as ΔS). ΔS reflects the ability of animals to discriminate the distance. For this task, we used juvenile rats which experienced neonatal social isolation. We found that isolated animals exhibited higher value of ΔS than control animals, indicating that distance detection ability is attenuated by neonatal social isolation (Miyazaki et al., 2012b). This behavioral effect with isolation is glucocorticoid signaling dependent, since application of RU486 during neonatal social isolation rescued this behavioral deficit (Miyazaki et al., 2012b).

These findings suggest that neonatal social isolation results in the deficits in whisker sensitivity and whisker-dependent behavior.

Conclusion

While numerous studies have revealed profound effects of stress on neural function, few have comprehensively related molecular, synaptic, and circuit deficits to behavioral aberrations (Feder et al., 2009; Kim and Diamond, 2002; Roozendaal et al., 2009). In series of our recent studies, we found that the stress produced by neonatal social isolation disrupts synaptic delivery of AMPA receptors, circuit formation in the cortex, and behaviors related to somatosensory function (Miyazaki et al., 2012b, 2013). We focused on plasticity in the barrel cortex since it is likely to play an important role in the integration of social information. This region is the primary sensory cortical area receiving input from whiskers, which are important for social interaction (Ahl, 1986; Strozik and Festing, 1981). Future studies should be focused on other brain areas such as medial prefrontal cortex which could process social information.

Previous human studies proposed the relation between the child maltreatment such as neglect and personality disorders which exhibit various deficits in social behaviors (Allen et al., 2013; Huang et al., 2012; Minzenberg et al., 2006). Interestingly, majority of patients with borderline personality disorders, who often experienced childhood maltreatment, exhibit the deficits in somatosensory processing (Pavony and Lenzenweger, 2014), potentially related to frequent self-injury. Our recent findings show that traumatic experiences during development, such as social isolation, can cause disruption of experience-dependent synaptic delivery of AMPA receptors, aberrant circuit formation in the somatosensory cortex, and behavioral abnormalities. It will be interesting to determine how and if miss-sensory processing leads to the emotional deficits of patients with the history of childhood maltreatment. These studies could lead to the effective treatment for psychiatric patients with the history of childhood maltreatment.

Neonatal Temperament: From Phenomenology to Mechanism

Hiroyuki Tsuchiya, Fukuda Hospital, Kumamoto, Japan

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Each neonate has a different personality/temperament that gradually develops during the perinatal period. I report that the crying duration at the first bathing is peculiar to each neonate. Neonates who cry longer at their first bathing cry longer at bathing on subsequent days. The crying tendency relates to the withdrawal behavior of neonates, which later will turn into fear and anxiety.

Fear and anxiety are personality/temperament traits that are, in part, regulated by the serotonin system. Genetic polymorphisms in proteins that participate in the synthesis, transport, and degradation of serotonin; and its receptors can alter neurotransmitter levels, especially in the amygdala, which is a central locus of fear and anxiety regulation. Analyzing the effects of these polymorphisms on traits is called the candidate gene approach.

Three representative approaches can be used to assess the role of genetic regulation of the personality/temperament traits. The first approach is the candidate gene approach, which is exemplified by the case of the serotonin system. The second approach includes whole genome sequence, microarray, and genome-wide association studies. The third approach is from the different standpoints: epistasis (gene–gene interaction), gene–environment interaction, and epigenetics. So far, none of the methods adequately explain the heritability of personality/temperament.

Analyzing the relationship between personality/temperament and genetic variability in infants is advantageous because infants' temperaments are simpler than adults' personalities and are not yet strongly affected by the environment. It is not clear whether any of the earlier approaches will elucidate the genetic mechanism of temperament or whether we will have to wait until other methods are developed. However, clarifying this mechanism will increase our understanding of neonates and human personality and will help us raise healthy children in the future.

Introduction

Are babies born with blank brains, or are they already prepared for life in the world? This was a question until several decades ago. According to recent knowledge, babies are born in the latter condition (Nolen-Hoeksema et al., 2009). Babies acquire genes from their parents; their neural network is thus already more or less prepared, their physical and mental development is affected by the environment *in utero*, and their genes and environment influence each other.

There are many works of substance on the developmental psychology of infants. On the other hand, recent developments in neuroscience have brought us important knowledge of human character based on brain imaging and neurogenetics. At least some of the phenomenology in developmental psychology could be explained by neuroscience. However, there have been few studies connecting these two approaches.

I have found (Tsuchiya, 2011, 2013) that there are some differences in the activity of babies when they encounter a new situation and have concluded that these differences may be connected to their neuroscientific background. Here, I review the relationships of neonatal temperament, and preceding studies on developmental psychology, neural circuitry, and neurogenetics. Personality is composed of both temperament and character traits. Temperament refers to an individual's innate emotional predisposition, while character is what we make of ourselves intentionally (Cloninger, 1998). However, in this review, the words personality, temperament, and character are used not according to these strict definitions.

Understanding neonates can provide important insight when we aim to comprehend what is human. We can appreciate our position in evolution when we compare the developmental position of neonates with the positions of other animals. Therefore, the study of the psychology of neonates is of interest to everyone in our society, not only to scholars of developmental psychology.

Birds are a species that has evolved to have individual differences in temperament/character (Barber, 1993). If individual birds have a different temperament/character, is it not possible that every human neonate has a different temperament/character?

The Emergence of Neonatal Temperament

At a large obstetric hospital, I observed the bathing of many neonates by trained nurses every day. Neonates were first bathed on day 2 after birth and were then bathed every morning until day 5 (the day they were discharged). I noticed that there was a tendency for the neonates who cried during the first bathing to cry on the following days. To investigate this hypothesis, I studied the duration of crying in individual neonates under as uniform conditions as possible. This study revealed that neonates who cried during their first bathing were apt to cry on the following days. The correlation coefficient of crying duration between days 2 and 3 was $r = 0.410$, $p < .001$, $n = 100$, and between days 3 and 4, it was $r = 0.506$, $p = .001$, $n = 38$ (Tsuchiya, 2011).

Crying is a negative mood expression classified as a withdrawal reaction of 'approach or withdrawal,' which is one of nine categories of infant behavioral styles and temperaments characterized by Chess and Thomas (1996). From day 2 to day 3, the number of neonates who did not cry during bathing increased, and the latency before crying increased. These observations may be related to another category of infant temperament, 'adaptability' (Chess and Thomas, 1996). Accordingly, even neonates who were 2 days old have their own innate temperament. How is this temperament designed

or inscribed in neonates? In the following section, I review the present status of research on neonatal temperament.

Observations from Developmental Psychology

In *Atkinson and Hilgard's Introduction to Psychology* (Nolen-Hoeksema et al., 2009), perspectives in psychology are summarized in five areas: the behavioral, cognitive, psychoanalytic, subjectivist, and biological perspectives. I start from the behavioral perspective and connect it to the biological perspective. The biological perspective explains and shows the background of human behavior. This approach may also reveal fundamental information related to psychiatric disorders.

Researchers have endeavored to clarify human character and characteristic differences among people. The five trait factors, often called the Big Five, are one of the achievements in this field. The five factors are Openness, Conscientiousness, Extroversion, Agreeableness, and Neuroticism, and they cover all aspects of personality (Nolen-Hoeksema et al., 2009). However, the factors are only applicable to personality in adults; until relatively recently, there has not been any appropriate approaches on temperament in children.

Chess and Thomas (New York Longitudinal Study)

One of the prominent works in child psychology was produced by Chess and Thomas (1996). They examined the characteristics of infants during the naturalistic observation of the infants' behavior (New York Longitudinal Study) and summarized the children's temperaments into nine categories: activity level, rhythmicity or regularity, approach or withdrawal, adaptability, threshold of responsiveness, intensity of reaction, quality of mood, distractibility, and attention span and persistence.

Using these categories, Chess and Thomas (1996) classified children into three groups: easy, difficult, and slow-to-warm-up. Approximately 40% of the subjects were easy children who were characterized by regularity in diurnal life, positivity to new stimuli, and high adaptability to change. Approximately 10% of children were difficult and exhibited irregularity, negativity, and nonadaptability. Slow-to-warm-up children (15%) showed negative responses to new stimuli but gradually showed positive responses to the same stimuli when they were encountered again. The remaining children (35%) were not categorized into any of the three groups.

Kagan and Colleagues

Kagan and colleagues studied the reactivity of infants to unexpected events from 4 months to 20 years of age (Kagan, 2010). They classified infants into four categories: high-reactive children (20% of the subjects) who were very excited when they encountered the unexpected stimuli, low-reactive children (40%) who were calm, distressed children (25%) who cried out loud but did not thrash their hands and legs, and aroused children (10%) who thrashed their hands and legs but did not cry out loud. The temperament of an infant, high or low reactivity, is apt to be kept until adolescence.

The response to unknown stimuli is regulated by the amygdala and the prefrontal cortex. The major functional roles of the amygdala are social behavior and the processing of novelty, emotion, and reward learning. The primate amygdala is a complex collection of 13 nuclei. The amygdala has an intricate internal architecture of discrete nuclei and widespread external connections (Schwartz et al., 2012). There are neuronal clusters in the amygdala that respond to any unexpected or unfamiliar event and alert other, nearby neurons to react appropriately. If the prefrontal cortex evaluates an event as being safe, it sends signals to the amygdala to stop the preparations for a fight or flight reaction.

Using functional magnetic resonance imaging (fMRI), Schwartz et al. (2012) showed that 4-month-old infants with high reactivity had greater activity in the amygdala in response to novel faces two decades later as adults. Infants with low reactivity showed the complementary pattern. The authors suggested that this temperamental difference already observed in early infants relates to individual differences in vulnerability and resistance to psychiatric disorders.

Rothbart and Colleagues

Rothbart (2011) summarized the development of temperament elements. Negative emotionality and orienting appear from the newborn period, frustration/anger and approach appear from 2 months, fear appears from 6 months, and effortful control appears from 10 months. These elements interact with each other. Differences in newborn orienting, activity, distress proneness, and soothability can be observed early in life and show some continuity with later temperament.

Continuity of Temperament in Life

The easy children (40% of children) in the Chess and Thomas study resemble the low-reactive children (40%) in the Kagan study; the difficult children (10%) of the former study look like the high reactives (20%) of the latter study. Temperament seems to persist from the infant period to at least adolescence. Roberts and DelVecchio (2000) reviewed 152 longitudinal studies, compiled 3217 test–retest correlation coefficients and concluded that "trait consistency increased from 0.31 in childhood to 0.54 during the college years, to 0.64 at age 30, and then reached a plateau around 0.74 between ages 50 and 70." The heritability of personality traits has been studied for a long time. Tellegen et al. (1988) reported heritability was estimated in the range 0.39–0.58.

From Phenotype to Genotype and Neural Circuitry: The Candidate Gene Approach

Cloninger's Model

Cloninger (1987) presented a hypothesis that related personality dimensions to neurotransmitters. There are three personality dimensions that are considered to be related to the brain's system of behavior: novelty seeking related to behavioral activation; harm avoidance related

to behavioral inhibition; and reward dependence related to behavioral maintenance. The corresponding neurotransmitters for these dimensions are dopamine, serotonin, and norepinephrine. This hypothesis showed a new avenue to understand the neural circuitry and neurotransmitters behind a behavior.

Hariri's Model

After Cloninger's proposal, Hariri (2009) reviewed the neurologic background of human behavior. He connected the behavioral trait, brain locus, neurotransmitter system, and functional polymorphism of the related genes. He identified three behavioral traits: trait anxiety, impulsivity, and trait anxiety and impulsivity. The responsible locus for trait anxiety is the amygdala, the neurotransmitter is serotonin, and the functional polymorphism of the serotonin system regulates this behavioral trait. Similarly, for impulsivity, the responsible locus is the ventral striatum, the neurotransmitter is dopamine, and the polymorphism of the dopamine transporter affects the dopamine level. For the combined anxiety and impulsivity trait, the responsible loci are the amygdala and ventral striatum; the polymorphism of the fatty acid amide hydrolase gene, which encodes an enzyme that mediates the hydrolytic breakdown of anandamide, reduces the enzyme activity and increases endocannabinnoid signaling.

Serotonin System

Among the personality traits, trait anxiety and its relationship to psychiatric status have been studied extensively, including the neurotransmitter involved and its genetic polymorphism and neural circuitry. Genetically manipulated mice models have also been examined (Fernandez and Gaspar, 2012; Li et al., 2012).

Neonates who are apt to cry at bathing (a new stimulation/situation) may be related to the difficult children in Chess and Thomas' study, Kagan's high-reactive children, and Rothbart's negative emotionality and trait anxiety. Accordingly, I review the serotonin (5-HT) system, which is a basis for trait anxiety.

5-HT is produced in neurons (Fernandez and Gaspar, 2012). In a presynaptic neuron, the amino acid tryptophan is hydroxylated to 5-hydroxy-tryptophan (5-HTP) by tryptophan hydroxylase 2 (TPH2). TPH2 is the rate-limiting enzyme for 5-HT synthesis in the brain (Berger et al., 2012). Then, 5-HTP is decarboxylated to 5-HT by aromatic amino acid decarboxylase. 5-HT is stored at the terminal of the presynaptic neuron, to be released by neurogenic stimuli in the neuron. At stimulation, 5-HT is released to the synaptic gap, where it binds to 5-HT receptors on the postsynaptic neuron. There are at least 17 distinct receptors, including 5-HT_{2A} (or expressed as HTR2A), 5-HT_{2C}, and 5-HT_3, that are located at the postsynaptic neuron surface. 5-HT_{1A} is located at both presynaptic (autoreceptor) and postsynaptic neurons (**Figure 1**).

Another protein involved in 5-HT neurotransmission is the 5-HT transporter (5-HTT). 5-HTT is located at the surface of presynaptic neurons and works to reuptake 5-HT released from the presynaptic neurons (Hariri and Holmes, 2006). 5-HTT removes 5-HT from the synaptic gap and returns it to the presynaptic neuron where 5-HT can be degraded or released later (Karg et al., 2011). Genetic polymorphisms of these proteins in the 5-HT neurotransmission system have been widely examined (Saudino and Wang, 2012). There are discrepancies among the reports: some show a correlation between the polymorphism and temperament or psychiatric conditions, and others do not. Among animal experiments, the congenic mouse model is a powerful tool in which the influences of a specific polymorphism of the target gene can be analyzed (Berger et al., 2012). However, the 5-HT system does not always produce the same results in different species: the elevation of 5-HT results in aggression in mice, but the consequences are the reverse in rats and silver foxes (Popova, 2006).

Tryptophan Hydroxylase 2

The effect of polymorphism of the TPH2 gene was described by Brown et al. (2005). They related the genotyping of the TPH2 gene to fMRI of the amygdala during a face-processing task in healthy human subjects, paying attention to the G(-844T) polymorphism, which has a high minor allele frequency (T allele = 38%). They found significantly higher bilateral dorsal amygdala activity in T allele carriers (G/T or T/T) than in G/G homozygotes.

The association of single-nucleotide polymorphism (SNP) in the TPH2 gene with the anxiety trait and with depression was studied in mice (Berger et al., 2012). The behavioral and neurochemical consequences of a C1473G polymorphism in the TPH2 gene were examined in the congenic mouse strain. Mice with a 1473 G/G polymorphism showed (1) a significant reduction of 5-HT synthesis, (2) a functional desensitization of 5-HT_{1A} autoreceptors without a reduction in basal or stress-induced 5-HT release, and (3) increased anxiety-related behavior without an alteration in depressive-like behavior.

Serotonin Receptor

5-HT_{1A} is expressed as a presynaptic autoreceptor on raphe neurons and as a major postsynaptic receptor in the hippocampal, cortical, and hypothalamic regions (Le François et al., 2008). The C(-1019)G 5-HT_{1A} promoter polymorphism is associated with serious depression and suicide. In depressed patients, the homozygous G(-1019) allele was enriched twofold vs controls (Lemonde et al., 2003). With this polymorphism, the function of the transcriptional factor NUDR, a 5-HT_{1A} receptor repressor in serotonergic raphe cells, is abrogated. Therefore, it has been proposed that the increased 5-HT_{1A} receptor expression, both pre- and postsynaptically decreased serotonergic neurotransmission, which is implicated in depression and suicide (Bismark et al., 2010). It is predicted that a significant portion (9.2%) of the individual differences in the trait anxiety is explained by this polymorphism (Hariri, 2009).

A relationship between the C(-1019)G 5-HT_{1A} promoter polymorphism and frontal brain electrical asymmetry has been shown (Bismark et al., 2010). In humans, the 5-HT_{1A} high-risk group (allele type GG) is associated with greater

Figure 1 A diagram showing the serotonergic synapse. In a presynaptic neuron, serotonin is produced from tryptophan via 5-hydroxy-tryptophan by tryptophan hydroxylase 2. Serotonin is released from the presynaptic neuron and binds to postsynaptic serotonin receptors. The re-uptake of serotonin into the presynaptic neuron is mediated by the serotonin transporter. Accordingly, the serotonergic signals from presynaptic neurons are regulated by the activities of tryptophan hydroxylase 2, serotonin receptors on presynaptic neurons (5-HT1A and 5-HT1B; autoreceptors) and post-synaptic neurons (e.g., 5-HT1A, 5-HT2A, 5-HT2C, and 5-HT3), and the serotonin transporter. 5-HT1A is located at the cell bodies, and 5-HT1B is located at the exon terminals (McDevitt, R.A., Neumaier, J.F., 2011. Regulation of dorsal raphe nucleus function by serotonin autoreceptors: a behavioral perspective. Journal of Chemical Neuroanatomy 41, 234–246). Gene polymorphisms in these proteins affect serotonergic signal transmission (see the main text). For serotonin receptors, only the representative receptors are shown. Adapted from Fernandez, S.P., Gaspar, P., 2012. Investigating anxiety and depressive-like phenotypes in genetic mouse models of serotonin depletion. Neuropharmacology 62, 144–154 and Hariri, A.R., Holmes, A., 2006. Genetics of emotional regulation: the role of the serotonin transporter in neural function. Trends in Cognitive Sciences 10, 182–191. For a further review, see the figures of Cools, R., Roberts, A.C., Robbins, T.W., 2007. Serotoninergic regulation of emotional and behavioural control processes. Trends in Cognitive Sciences 12, 31–40 and Canli, T., Lesch, K.P., 2007. Long story short: the serotonin transporter in emotion regulation and social cognition. Nature Neuroscience 10, 1103–1109. Trp, tryptophan; Tph2, tryptophan hydroxylase 2; 5-HTP, 5-hydroxy-tryptophan; 5-HT, serotonin; HTR1A, serotonin receptor 1A; 5-HTT, serotonin transporter.

right frontal activity compared with the low-risk groups (allele types CC and CG). Greater right frontal activity is also associated with individuals who have a history of major depression disorder compared with individuals without such history. Kishi et al. (2011) showed an association between C(-1019)G 5-HT_{1A} SNP and bipolar disorder by meta-analysis.

In mouse experiments, Li et al. (2012) injected recombinant adenoviruses containing a 5-HT_{1A} antisense sequence or a 5-HT_{2C} sense sequence into the amygdala. In the 5-HT_{1A} antisense sequence-injected mice, the reduction of 5-HT_{1A} receptors in the amygdala increased anxiety-like behaviors. In the 5-HT_{2C} sense sequence-injected mice, the increase of 5-HT_{2C} receptors in the amygdala also increased anxiety-like behaviors.

A relationship between different types of thinking (i.e., holistic vs analytic) and the C(-1019)G 5-HT_{1A} polymorphism has also been reported (Kim et al., 2010). These researchers suggested that cultural differences influence the effect of polymorphism. Koreans with the GG genotype showed higher attention to context than Koreans with the CC and CG genotypes. In contrast, European Americans with the GG genotype showed lower attention to context than European Americans with the CC and CG genotypes. These researchers concluded that the same genetic predisposition can result in divergent psychological outcomes, depending on an individual's cultural context and that this result shows a gene by culture interaction effect, which is an example of gene–environment interaction described later. Kim et al. (2010) also highlighted the difference in the allelic distribution between Koreans and European Americans. A higher proportion of the population has the GG allele in Koreans than in European Americans, which is consistent with previous reports.

The crystal structure of 5-HT receptor has been reported (Wang et al., 2013).

Serotonin Transporter

Meta-analysis has shown that the promoter region of the 5-HTT gene (5-HTTLPR; 5-HTT gene-linked polymorphic region) genotype polymorphism affects the activation of the amygdala (Munafò et al., 2008). The 5-HTTLPR polymorphism is a short (S) allele comprised of 14 copies of a 20–23 base pair repeat unit and a long (L) allele comprised of 16 copies. This polymorphism affects the transcription rate of the gene: the S allele is transcriptionally less efficient than the L allele. People with the short (SS and SL, combined) genotype and a European ancestry showed higher amygdala activation than those with the long (LL) genotype when emotional facial expressions, pictures, and words were used as stimuli. The neuroimaging technologies that were used in the studies included in the meta-analysis were fMRI, positron emission tomography, and perfusion MRI. However, this association, i.e., higher activation in the S genotype group than in the LL group, may be opposite (the LL genotype is associated with higher amygdala activation) in people of Asian ancestry. The effects of genes and environment in 5-HTTLPR genotype polymorphism need further examination.

Furthermore, 5-HTTLPR polymorphism alters the neural circuitry regulating emotion. The S allele form is associated with increased negative emotionality and stress vulnerability, which is related to the diminished communication between the amygdala and specific regions of the prefrontal cortex, namely, the sub- and supragenual anterior cingulate cortex. Almost 30% of the variance in harm avoidance is predicted by the functional connectivity of the amygdala and the rostal subgenual anterior cingulate cortex (Pezawas et al., 2005; Hariri and Holmes, 2006). Meta-analysis has shown that 5-HTTLPR moderates the relationship between stress and depression, with the S allele being associated with an increased risk of developing depression under stress (Karg et al., 2011).

As shown earlier, neonatal/infant temperament especially withdrawal, anxiety, and/or fear may be explained by neurotransmitters and their genomic variants in serotonin system. Research has been performed on the role of the serotonin system components in temperament; however, no definitive conclusions have been reached, as some studies show positive results, and other studies show negative results. A meta-analysis showed that a role for variants in the serotonin system could have some value (Saudino and Wang, 2012).

Clinical Significance of Serotonin Transmission

The aim of this review is not to express the pathological condition of temperament, but it is still important to mention this aspect. The 5-HT system is not simple. Different effects of 5-HT are observed in different species (Popova, 2006; discussed in the Serotonin System section), and changes in 5-HT transmission result in anxiety (increased 5-HT) or depression and panic disorder (decreased 5-HT) (Cools et al., 2007). Anxiety is treated with benzodiazepines to reduce 5-HT transmission; depression and panic disorder are treated with selective serotonin reuptake inhibitors to increase 5-HT transmission.

Dopamine System

The association between polymorphism of dopamine system genes and personality traits in healthy Caucasians has been reported (Kazantseva et al., 2011). The transporter gene (SLC6A3) polymorphism has been associated with persistence, and the dopamine D2 receptor gene (DRD2) has been associated with neuroticism. Concerning the neural circuitry in dopamine system, it has been suggested that decreased Dopamine D2 receptor availability in the striatum causes a predisposition to reward-related traits and disorders associated with DRD2 gene polymorphism.

Gene–Environment Interaction and Epigenetics

Gene–Environment Interaction

The role of environment in the development of personality has been clarified. Some authors classified approaches in this area, particularly influences on adolescent depression, as genetic, environmental, and gene–environmental (Eley et al., 2004). Environmental influences may be divided into child-specific and family-general risks. The former includes life events and peer relationship problems; the latter includes parental psychopathology, low socioeconomic status, and family-based stressful life events. Gene–environmental interaction may also be divided into two approaches: an indirect approach, where phenotype heritability varies as a function of environmental risk, and a direct approach, e.g., the interaction between adverse life events and the S allele of the 5-HTTPLR on depression and suicide. 5-HTTPLR allele analysis revealed an association with adolescent depression: for females within the high environmental risk group for depression, an increase in the number of S alleles (SS, SL, or LL) increased the frequency of the depression (Eley et al., 2004). Comparing the high and low environmental risk groups, girls with SS alleles in the former group exhibited a 2 times greater risk of depression than the latter group. This observation may be an example of a direct effect of gene–environmental interaction. If the environmental risk is low, even girls with SS alleles (genetically high risk adolescents) do not get depression with high frequency.

In addition, in rhesus monkeys, an interaction between rh5-HTTLPR (a rhesus monkey ortholog of human 5-HTTLPR) and environment has been reported (Champoux et al., 2002). Mother- and nursery-reared animals with the heterozygous 5-HTTLPR form SL demonstrated an increased affective response relative to LL homozygotes. Nursery-reared SL infants exhibited lower orientation scores than their LL counterparts (Champoux et al., 2002).

Gene–environment interaction is observed in many areas. The relationship between body mass index (BMI) and physical activity is one example. The heritability of BMI is moderated by physical activity: the higher the level of physical activity, the smaller the genetic influence on BMI (van Dongen et al., 2012).

Epigenetic Regulation of the Glucocorticoid Receptor

Meaney and colleagues (Weaver et al., 2004; Meaney and Szyf, 2005; Meaney, 2010) reported the epigenetic regulation of the glucocorticoid receptor (GR) gene. There are two types of mother rats in the Long-Evans outbred strain: mother rats that rear their pups with lots of licking and grooming (LG) and mother rats that do not. The female offspring of each type of mother grow up to be mothers with the same style of child-rearing as their mothers. Increased LG by mother rats in the first week of life alters the DNA structure at a GR gene promoter in the hippocampus of the offspring. A difference in the DNA methylation at a GR gene promoter in the offspring of high- and low-LG mothers emerges over the first week of life: low methylation is observed in the pups of high-LG mothers, and high methylation is observed in the pups of low-LG mothers; cross-fostering reverses the methylation states. In the neonatal pups, increased LG is associated with hippocampal 5-HT turnover and the activation of a 5-HT_7 receptor, which is coupled to the induction of the transcription factor NGFI-A and its cofactor CREB-binding protein. The CREB-binding protein enhances the ability of NGFI-A to bind and activates GR gene transcription. In addition, increased histone acetylation, which is a marker of active chromatin, and greater binding of NGFI-A protein to the hippocampal exon 1_7 GR gene promoter are observed in the adult offspring of high-LG mothers compared with the adult offspring of low-LG mothers. The high-LG offspring show significantly increased hippocampal GR mRNA expression, enhanced glucocorticoid negative-feedback sensitivity, and decreased hypothalamic CRH mRNA levels. As adults, the offspring of the high-LG mothers show increased anxiolytic behavioral responses to stress. McGowan et al., (2009) revealed that the same mechanism worked in humans who were abused in childhood, which suggests a common effect of parental care on the epigenetic regulation of hippocampal GR expression.

An adverse environment during infancy affects at least the serotonin system and glucocorticoid receptor regulation. The influence in the infant period appears even in later life.

Discussion – Roles of Heritability on Personal Traits

Cloninger (1987) presented a hypothesis on the relation of personality dimensions to neurotransmitters, which is a milestone in the biological study of human personality. Primary characters such as vigilance and wariness are highly beneficial and are conserved in animals (Nettle, 2006). These character traits may be related to approach and withdrawal in human neonates, fear and anxiety in infants, and neuroticism, one of the Big Five trait factors in adults. Neonatal traits appear via a biological mechanism. Approach and withdrawal may be regulated by the genes of the serotonin system (e.g., tryptophan hydroxylase gene, serotonin receptor gene, serotonin transporter gene) and by specific brain loci (amygdala and prefrontal cortex). The appearance of a neonatal trait may be controlled by the regulation of neurotransmitter genes and the neural circuitry where the neurotransmitters work. Other traits expressed by Chess and Thomas (1996) may be not essential to life, and elucidating a similar responsible set for the trait (the neurotransmitter and the neural circuitry) may thus be more difficult than for the case of approach and withdrawal.

Tooby and Cosmides (1992) suggested that from an evolutionary perspective, personality variation in human individuals is neutral. Nettle (2006) noted that heritable variation is ubiquitous in animals, including humans, and that each of the Big Five personality factors has its own benefits and costs (trade-offs). An example of animal behavioral variation is the exploitation observed in the great tit (*Parus major*), which is consistent within individuals and is heritable in the same range as human personality dimensions.

To examine the relationship between children's early family experience and their later intellectual growth, the vocabularies of children were studied from 1 to 3 years of age (Hart and Risley, 1995). The results showed that the most important factors for language acquisition are the economic advantages of the child's home and the frequency of the child's language experiences. Children born into homes with fewer economic resources learn fewer words, have fewer experiences with words through interactions with other people, and acquire a vocabulary of words more slowly. Although the genetic participation rate may differ from character and intellectual growth, such as language, this report suggests that intervention in character development may also be possible. If infants have high reactivity, we may intervene in their development to not reinforce that character because extremely high reactivity may not only make them unhappy but it may also be related to morbid status, such as unipolar major depression or bipolar disorder.

Schwartz et al. (2012) reported the role of gender in predicting the effect of infant temperament on amygdala reactivity in adulthood. Male adults who were high-reactive infants showed high levels of reactivity to novel faces in the amygdala. In contrast, females showed less reactivity, which may be explained by the effect of estrogen. The testosterone level is high even in neonatal males and may affect neonatal traits, for example, through dopamine neurotransmission (Kazantseva et al., 2011). Men have markedly greater dopamine release than women in the striatal regions (Munro et al., 2006).

It is generally accepted that approximately 50% of human character is controlled by heritability (e.g., Tellegen et al., 1988; Nolen-Hoeksema et al., 2009). There are several different approaches to assess the role of heritability (Plomin, 2013). The primary approach is through candidate genes, as in the case of the serotonin system in fear and anxiety. The second approach includes whole genome sequence, microarray, and genome-wide association studies. These methods are based on the idea that an accumulation of very small genetic differences (e.g., SNPs) can affect character traits. The third approach includes epistasis (gene–gene interaction), gene–environment interaction, and epigenetics.

A large genome-wide meta-analysis study of association on temperament scales involving more than 11 000 adults was reported (Service et al., 2012). However, in this large study, less than 1% of the variability in any temperament dimension

was due to a risk score derived from SNPs showing association to the temperament dimensions, although the temperament scales are considered heritable.

Each genetic method for assessing the heritability of human character has its limitations. For example, in the candidate gene approach, we often do not have strong hypotheses as to which genes are candidates. A personality trait may be a function of hundreds of different genes (Rutter, 2011). These genes are both specific and redundant and can participate in cross-talk with each other. According to Rothbart (2011), there are interactions (either facilitation or inhibition) among temperament elements in infants. So far, neither method can adequately explain heritability. This situation is observed for other human traits that are considered to be multifactor inheritance (e.g., body height). It is called 'missing heritability' (Maher, 2008; Manolio et al., 2009).

A comparison between an infant's temperament assessed using any of Chess and Thomas's, Kagan's, or Rothbart's classifications and the results of polymorphism in relevant genes, as in the case of approach or withdrawal and the serotonin system, may be very interesting. Analyzing the relationship between temperament/personality and genetic variability in infants is advantageous because infants' temperaments are simpler than adults' personalities and are not yet strongly affected by environment. Assessing crying time in neonates has further merits: the method is simple, not painful, and does not depend on self-reported inventories.

It is not known whether any of three approaches described earlier will elucidate the genetic mechanism of temperament or whether we will have to wait until other methods are developed. However, clarifying this mechanism will increase our understanding of neonates and human personality and will help us raise healthy children in the future.

Neo-Piagetian Theories of Cognitive Development

Michael F Mascolo, Merrimack College, North Andover, MA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Neo-Piagetian theories of cognitive development emerged as attempts to preserve core theoretical and empirically supported aspects of Jean Piaget's seminal theory of intellectual development while addressing criticisms leveled against the theory. Neo-Piagetian theories preserve three basic ideas from Piaget's theory: (1) the unit of cognitive analysis is the *scheme* or *psychological structure*; (2) psychological structures undergo *qualitative transformation* over time; and (3) higher order structures develop through the *differentiation* and *coordination* of lower level structures. After a brief discussion of similarities and differences among prominent neo-Piagetian theories, one representative approach (dynamic skill theory) is discussed in depth. The discussion concludes with a description of recent advances in neo-Piagetian systems theory.

In his theory of intellectual development, Jean Piaget articulated a series of questions and ideas that launched the field of cognitive development. Piaget's legacy is most keenly reflected in neo-Piagetian theories of development. Neo-Piagetian models emerged in the 1970s and 1980s address criticisms leveled against Piaget's theory while simultaneously maintaining core principles (Case, 1985; Commons et al., 1998; Demetriou et al., 2010; Fischer and Bidell, 2006; Halford, 1993; Pascual-Leone, 1970).

Piaget's Theory of Intellectual Development

According to Piaget, knowing is a form of acting (de Ribaupierre, Piaget's Theory of Cognitive Development). The basic unit of cognitive analysis is the *scheme*, which refers to a structured system of action or thought. *Schemes* function through the dual processes of *assimilation* and *accommodation*. *Assimilation* refers to the process by which to-be-known objects are incorporated into existing schemes; *accommodation* reflects the simultaneous processes of modifying a scheme to incorporate the object. For example, to grasp a rattle, an infant incorporates (assimilates) the rattle into her organized grasping action (scheme) while simultaneously modifying (accommodating) her scheme around the particular contours of the incorporated object.

Piaget maintained that the structure of a child's schemes undergoes transformation in a series of broad-based *stages* over time. For Piaget, stages exhibit several important properties. First, each stage reflects a qualitatively distinct type of thought or action. Children are not simply little adults; they think and act in fundamentally different ways. Second, stages form a *hierarchical progression* with later stages building upon earlier ones. Third, the stages form a *universal* and *unidirectional* sequence regardless of culture or the content of thought. Fourth, Piagetian stages form *structures d'ensemble* (i.e., 'structures of the whole') – generic structures that have wide application to broad ranges of cognitive tasks and conceptual domains. Although Piaget acknowledged the phenomenon of *décalage* – the finding that structurally similar abilities often develop at different times, he nonetheless held that within a stage, systems of thought form broad, integrated wholes.

Piaget suggested that in infancy, schemes operate within the *sensorimotor stage* of development. Sensorimotor schemes consist of organized systems of *action* on objects. During this time, infants cannot form representations (images) of events without direct sensory contact. Symbolic thought emerges between 18 and 24 months of age with the onset of the *preoperational stage*. At this stage, children form representations of events (e.g., words, images) but cannot manipulate them in logical or systematic ways. Children gain the capacity for pretend play and deferred imitation. During the concrete operational stage (around 6–7 years), with the capacity to think logically using concrete images and representations, children can successfully perform a variety of logical tasks (conservation, class inclusion, seriation, transitivity, etc.). In the formal operational stage (adolescence onward), individuals gain the capacity to think logically using abstract ideas free from particular concrete content.

Although Piaget is most closely associated with his stage theory, the concept of *equilibration* provides the foundation of his theory. Equilibration refers to an inherent, self-regulating, compensatory process that motivates the construction of novel patterns of thought over time. *Equilibrium* occurs when an individual is able to assimilate an object to a scheme while accommodating the scheme to the object. *Disequilibrium* occurs when assimilation and accommodation fail; a mismatch arises between object and scheme. Disequilibrium prompts reorganization (differentiation and integration) of schemes in an attempt to restore equilibrium. For example, recognizing an object as a *bunny* involves assimilating a rabbitlike object into an existing *bunny* scheme. Although initial attempts to assimilate a *kitty* into the *bunny* scheme may be successful, eventually, such attempts will fail as children sense the conflict between the kitty's features and their representation of a bunny. One way to restore equilibrium involves differentiating the initial *bunny* scheme into two separate schemes – one for bunnies and one for kitties. Developmental change occurs through *equilibration*.

Critiques of Piaget's Theory

Table 1 describes eight critical issues that have emerged with regard to Piaget's theory. Regarding Piaget's stage theory, Demetriou (2006) stated, "whenever a replication study

Table 1 Four neo-Piagetian theories

Issue	*Piagetian principle*	*Problem*	*Pascual-Leone*	*Case*	*Fischer*	*Demetriou*
Unit of psychological analysis	Figurative and operative schemes basis in action and internalized action	Difficulty specifying scheme independent of task; task ability changes with task	First-order subjective operators (schemes) and second-order *metasubjective* operators	Executive control structures	Skill: Capacity to control elements of acting, skill and feeling within particular contexts, and psychological domains	Processing potentials Hypercognitive system Specialized structures of thought
Nature of change	Qualitative structural change	Evidence of higher order abilities at lower stages	Qualitative changes in structure; quantitative changes in working memory capacity	Qualitative changes in structure; quantitative changes in working memory capacity	Qualitative and quantitative transformation of skills in context	Structural change in specialized structures of thought; quantitative change in processing potentials
Structures D'Ensemble	Broad-based stages of structures of logicomathematical Intelligence	Decalage between emerging abilities; age of emergence varies with area, task, context, etc.	Task analysis yields structure of actions needed to perform a given task	Development organized around series of different central conceptual structures	Development tied to local domains, tasks, and contexts; variation is rule rather exception; task analysis indicates structure	Specialized structures of thought (e.g., class, causality, number, space, verbal, social domains of thought) each mediated by their own symbol systems
Hierarchical progression	Logical skills involve hierarchical progression	Predicted sequences do not always hold	Tied to task and nature of task sequence	Hierarchical progression within development central conceptual structures	Higher order skills build on lower level skills; multiple paths to any particular form of skill	Hierarchical progression within development central conceptual structures
Universality	Single universal sequence of stages	Variation in particular trajectories by culture; final stages not always reached	Tied to task and nature of task sequence	Different central conceptual structures develop through fixed and universal stage structures	Alternative pathways of structural change in different domains, tasks, contexts, cultures, and individuals	Different central conceptual structures develop through fixed and universal stage structures
Change processes	Equilibration Differentiation and integration to adapt to cognitive conflict; *maturation* of physical structure; active *experiencing* of world; *social transmission* of cultural knowledge	Difficulty specifying how process of differentiation arises from cognitive conflict	*Constructive operators* foster change: *Content operator* (*C*) produces accommodative change as schemes encounter conflict; *learning operator* (*L*) coordinates schemes into higher order units; *mental energy* (*M*) indicates central computing space; *interrupt operator* (*I*) inhibits irrelevant schemas	Hierarchical coordination of executive control structures; changes in working memory engendered by brain development and myelinization	Differentiation and coordination of lower level actions into higher order skills; social scaffolding and contextual support; discontinuities in brain growth and development	Change in speed of processing, control of processing, and representational capacity; metarepresentation and symbolic individuation
Role of affect	Affect merely provides energetics of adaptive action; schemes do the work of adaptive action	Affect more differentiated and plays stronger role than Piaget suggested	*Affect operator* (*A*): Affective schemes activate cognitive schemes, and vice-versa.	Cognition and affect are generated by different systems that influence each other over time	Affect plays central role in organizing consciousness, psychological structures, and the pathways through which they develop	Self-oriented processes generate emotional feelings
Role of context and culture	Sensory and social conflict stimulates development	Change context, change skill; scaffolding	Change arises through dialectical exchange between organism and physiosocial context	Children must have access to cultural activities to construct central conceptual structures	Context and cultural tools play direct role in formation and functioning of skill	Quantitative differences in processing potentials and content among cultures

remained close to the original Piagetian conditions, the same phenomena were observed in more or less the same way at more or less the same age." However, when researchers modified the nature or complexity of Piagetian tasks, children showed evidence of logical abilities earlier than Piaget indicated (Bryant and Trabasso, 1971). Research shows that children often pass structurally similar tasks at different ages (e.g., mass is conserved before volume; Gelman and Baillargeon, 1983). Studies show that children function at higher levels when provided with contextual support than in the absence of support (Fischer et al., 1993; Vygotsky, 1978). Cross-cultural research indicates variation not only in the age at which children are able to perform Piagetian tasks, but also in the form of thinking itself (Saxe, 1991). Other theorists suggested that Piaget's concepts of assimilation and accommodation were vague and difficult to assess (Klahr and Wallace, 1976). Still others suggested that the theory failed to account for the importance of affect (Fischer et al., 1990) and language (Matusov and Hayes, 2000) in the process of development.

Neo-Piagetian Models of Development

Neo-Piagetian models of development preserve three core aspects of Piaget's theory: (1) knowing involves the invocation of schemes or psychological structures; (2) that psychological structures undergo *qualitative transformation* in development; and that (3) higher order forms of psychological structure arise through the *differentiation and hierarchical coordination* of lower level schemes. Table 1 and Figure 1 show similarities and differences among prominent neo-Piagetian approaches.

Pascual-Leone's Theory of Constructive Operators

Juan Pascual-Leone (1970) launched the traditional of neo-Piagetian theories. Drawing on information processing psychology, Pascual-Leone proposed his *theory of constructive operators* (*see* Conscious Control during Childhood, Development of; Executive Functions during Childhood, Development of). Pascual-Leone differentiated two basic categories of operations. These include *subjective operators* (akin to Piagetian schemes) and *metasubjective operators*. In any given situation, a variety of first-order operative and figurative (content) schemes are activated. In the traditional conservation task, activate schemes for understanding height and width of the beakers, the fluidity of liquid, and so forth. The multiplicity of schemes sets the stage for the production of cognitive conflict. For example, a child may notice that when pouring water from a tall and thin beaker to a short and wide one, the amount of water appears to change. Metasubjective operators are second-order processes that operate on first-order operators (schemes). Pascual-Leone differentiated a series of metasubjective operators, the most prominent including the *Content* (*C*), *Learning* (*L*), *Mental Energy* (*M*), and *Interrupt* (*I*) operators. (Other

Figure 1 Comparison of levels hypothesized by Neo-Piagetian theories of development.

operators include the Content (*C*), Space (*S*), Field (*F*), and Affect (*A*) operators.) Metasubjective operators function to create new schemes in order to resolve contradictions among competing schemes. For example, the *C* operator adjusts the content of schemes to accommodate to novel experience. The *L* operator creates higher order schemes by coordinating two or more activated schemes (e.g., coordinating schemes for judging *height* and *width* into an understanding that changes in height are compensated by changes in width). The *I* operator *inhibits* the activation of schemes that are irrelevant to a given task (e.g., inhibiting the tendency to rely on perceptual differences in height to make judgments about volume in the conservation task). These operators work together adaptively in the context of cognitive conflict to construct novel schemes that function to resolve cognitive contradiction.

Perhaps the most frequently invoked construct proposed by Pascual-Leone is the concept of mental energy or *M space*. *M* places a limit on the amount of information that can be held in mind at any given time. Pascual-Leone proposed that maturation of the capacity of the *M* operator is the primary source of cognitive developmental change (*see* Short- and Long-Term Memory during Infancy and Early Childhood across Cultures). In development, increases in M capacity allow children to hold increasing numbers of schemes in mind while performing cognitive tasks. According to Pascual-Leone and Johnson (1991), between birth and 3 years of age, sensorimotor M space (e) increases by one scheme every 4 months. For symbolic schemes, the capacity of the M operator (k) increases by one scheme every 2 years from 3- to 15-years of age. Thus, as indicated in **Figure 1**, total *M* space is calculated as the sum of *M* space required for sensorimotor (e) and symbolic (k) schemes ($M = e + k$).

To understand developmental changes in children's task performance, it is necessary to understand the nature and number of schemes that children must hold in mind in order to perform different types of tasks. To achieve this goal, a researcher can perform a task analysis, which involves identifying the component operations and representations required to complete a task. Having performed a task analysis, a researcher can identify the number of schemes necessary to perform the task successfully. Developmental change does not occur in a holistic, stagelike matter. At any given point in time, a child's cognitive abilities are defined by a child's available schemes, the capacity of *M* space, and the cognitive demands of particular tasks.

Case's Staircase Model

Case's (1985, 1991) model of cognitive development builds upon and extends Pascual-Leone's approach. Case's model contains three main components: The theory of *executive control structures*, the invocating of *working memory capacity* as the source of conceptual change, and developmental change organized around *central conceptual structures*. For Case, the primary unit of thinking is the executive control structure, which consists of "an internal mental blueprint, which represents a subject's habitual way of construing a particular problem situation, together with his or her habitual procedure for dealing with it" (Case, 1985: p. 68.). The concept of executive control structure incorporates both the figurative and operative aspects of thinking into a single structure. Similar to Piaget, Case proposed that executive control structures develop through four basic stages. As indicated in **Figure 1**, these include the *sensorimotor* (birth to 18 months), *interrelational* (1½–5 years), *dimensional* (5–11 years), and *vectoral* (or abstract dimensional) stages (11 years through adulthood). Within each stage, control structures develop through four levels: *predimensional*, *unidimensional*, *bidimensional*, and *integrated bidimenional*. The substages develop in a cyclic and iterative way in that the *last* substage within each stage (the integrated bidimensional substage) corresponds to the *first* substage (*predimensional*) of the next broad stage of thought. (The cyclic nature and development of executive control structures will be explained further in the discussion of Fischer's (1980) dynamic skill theory.) Case proposed that developmental progressions are organized around different *central conceptual structures* (Case et al., 1996). These consist of "networks of semantic nodes and relations that have an extremely broad (but not system-wide) domain of application" (Case et al., 1996: p. 5). Central conceptual structures organize a suite of executive control structures around a common core. Case and his colleagues amassed evidence for the existence of a series of central conceptual structures, including those for *quantity*, *space*, *social relations*, *narrative*, *motor action*, and *music*.

Like Pascual-Leone, Case held that changes in attentional capacity are responsible for stage progression. Case suggests that processing capacity involves the integration of two basic components: *operating space* and *short-term storage space*. Operating space refers to the capacity required to execute *goal-related operations*. Short-term memory space corresponds to the number of *representational schemes* on which an individual can focus in a single act of centration. For example, the act of counting the number of items on a grocery list is composed of two integrated components: the goal-related *operations* corresponding to counting each item, and the monitoring of representations that arise from successive counts ('1 item,' '2 items,' etc.). Counting acts require *operational* space whereas the monitoring the representational outcomes requires *short-term storage space*. Case held that *total* processing capacity (i.e., operating space plus short-term storage space) does *not* change in ontogenesis. Instead, he suggested that the ability to execute operations becomes increasingly efficient over time, which frees processing space for short-term storage. Case suggested that increasing efficiency of executive operations results from changes in brain structures that mediate the processing of information, as well as increasing myelinization of neuronal axons.

Halford's Relational Complexity Model

Halford's (1993; Halford et al., 2012) relational complexity model of cognitive development is based on the idea capacity limitations in working memory are not simply a function of the number of representational units that can be retained at any given time, but instead reflect the complexity of the *relations between* representational units. Halford's relational complexity metric is defined in terms of *arguments* and *relations*, and can be represented as follows: RELATION (argument$_i$, argument$_j$, etc.). Binary relations include relations between two arguments;

ternary relations involve three arguments; quaternary relations involve four interrelated arguments, and so forth. For example, the relation LARGER-THAN (dog, cat) expresses the binary relation 'dog is larger than cat'; the ternary relation ADDITION (1, 3, and 5) indicates an additive relation between three numbers. Halford and his colleagues have assessed children's capacity to perform different types of representational tasks (e.g., transitivity, class inclusion, hierarchical classification, cardinality, etc.) that vary in relational complexity. They found that relational complexity was directly related to the age of acquisition of target skills (Andrews and Halford, 2002). Halford has shown that unlike performance on Piagetian tasks, (which show decalage in different conceptual domains) children acquire the capacity to perform tasks at the same level of relational complexity at the same time, regardless of domain or task variables (Halford and Andrews, 2006). Halford's relational complexity theory is not a stage theory in the sense of Piaget's theory. Instead, like Pascual-Leone's theory, Halford is able to track gradual developmental changes in children's thinking by identifying the relational complexity of the tasks that they are able to perform. However, like Case's (1985) theory, Halford's theory predicts that tasks reflecting the same level of relational complexity will be passed around the same age.

Demetriou's Analysis of the Developing Architecture of Mind

For over 25 years, Andreas Demetriou et al. (2010) have worked toward a comprehensive model of the architecture of the developing mind. As indicated in **Figure 2**, Demetroiu suggests that the human 'mind' is organized into three levels of interacting systems: *Specific structural systems*, *hypercognitive* systems, and *core capacities*. Specific structural systems consist of organized domains of representation and operational abilities and are constituted by different symbol systems. These include *categorical, verbal, quantitative, causal, spatial,* and *social* systems of operations. Hypercognitive systems consist of systems of higher order control structures (sometimes called meta-cognitive structures) that govern self-understanding, self-monitoring, and self-regulation. Hypercognitive processes map elements of specific structural systems onto each other in the constructive integration of everyday activity. Core capacities include *processing speed*, *control of processing,* and *storage*. Processing speed refers to the tie needed for the system to process the meaning of information; control functions regulate the activation and inhibition of relevant and irrelevant information in any given task. Storage is mediated by a multidimensional system for retaining and operating on information in real time Baddeley's (2012). Information is retained in specialized information processing buffers (e.g., phonological, visual) where they are operated on by central executive processes.

Figure 2 Demetriou's model of cognitive development.

Demetriou suggests that each of these three systems undergoes systematic change in development. Specific domains of thought (structural systems) undergo qualitative change in accordance with Case's (1985) model. To illustrate, developmental changes in the quantitative structural system are indicated in **Figure 1**. Hypercognitive processes also change. For example, children under the age of about 7–8 years show limited awareness of the nature and functioning of their own psychological processes. After about 7–8 years, children use their awareness increasingly of their psychological states to predict, plan, and regulate their thinking and acting. Finally, core capacities show steady change over time. Demetriou and his colleagues (Demetriou and Mouyi, 2011) have shown that core capacities (processing speed, control processing, and information storage) increase systematically with age. While such provide the broad resources for the construction of higher order thought structures, the processes of *metarepresentation* and *symbolic individuation* mediate their actual construction. Metarepresentation processes identify and abstract similarities between mental experiences (integration); symbolic individuation processes tag novel mental experiences (differentiation).

Dynamic Skill Theory: A Neo-Piagetian System Model Psychological Development

The discussion now turns to an in-depth illustration how neo-Piagetian theory – in particular, Fischer's dynamic skill theory (Fischer, 1980; Fischer and Bidell, 2006; Mascolo and Fischer, 2015) – accounts for structural changes in psychological development. In Fischer's (1980) approach, a *skill* refers to an individual's capacity to control elements of thinking, feeling, and acting within specified contexts and within particular task domains. As in Case's (1991) theory, a skill is a type of *control structure*; it refers to the configuration of action over which an individual exerts control within a given context. The concept of skill differs from the Piagetian notion of scheme. Unlike the concept of scheme, skills are not properties of individuals. Instead, they are properties of *individuals-within-contexts*. Changes in context typically result in change in behavior, and vice-versa. Action is always a joint product of person and context.

Contexts differ in how they contribute to individual activity. Skill theory differentiates three types of contexts*: Low support, high support,* and *scaffolding*. By orienting attention to important features of a task, high support contexts support the production of a person's *optimal level* of functioning – the *highest* level one

can perform on one's own. In low support contexts, individuals operate at their everyday *functional* levels, typically several levels lower than their optimum. For example, students who are able to understand complex ideas while attending a lecture (high support) often find that their understanding declines when studying at home (low support). This occurs because at home, students do not benefit from the support of a lecture to orient their attention toward central ideas.

A third type of context provides individuals with *scaffolding*. Scaffolding occurs when a more accomplished individuals break down, structure, direct and assist a less expert person in completing a task (Mascolo, 2005). Scaffolding differs from high support. Under conditions of scaffolding, another person carries part of the load of a task; in high-support situations, individuals complete tasks *on their own*, albeit under conditions that orient attention. Under scaffolded conditions, individuals perform at levels that exceed their optimal levels, thus fostering learning and development (Vygotsky, 1978) (*see* Vygotsky's Theory of Cognitive Development; Neo-Vygotskian Developmental Theory).

A second way in which the concept of skill departs from Piagetian theory is that skills are not general structures. There are no general, decontextualized, or all-purpose skills. Skills that operate within different conceptual domains (e.g., conservation, classification, reading words, social interaction, etc.) develop somewhat independently and at different rates. Development in domain (e.g., conservation) does not necessarily predict development in other domains (e.g., classification), or even in conceptually similar tasks (conservation of number vs conservation of volume). It is only possible to track developmental sequences for particular skills within particular domain, social contexts, and assessment conditions.

The Web of Development

Given the above, it follows that individuals never operate at any single level of development. Instead, they operate within a *developmental range* – a series of levels that vary with task, domain, context, emotional state, and so forth. Given such dynamic variation, there can be no broad-based stages of development. It is thus not helpful to think of a person or a person's abilities as being 'in a stage' of development. Development does not move through a series of fixed steps; development operates more like a *constructive Web*. As indicated in Figure 3, a constructive Web is composed of multiple converging and diverging pathways or strands. Such strands can represent the developmental courses of different individuals, different domains of thought in groups of children, or different domains of skill within the same individual (e.g., writing, arithmetic, social skills). Within particular individuals, skills in different domains develop along different pathways. For example, writing and arithmetic skills tend to develop along relatively independent pathways. However, skills for responding in writing to math problems require convergence among different reading, writing, and arithmetic skills.

Tracking the Development of Psychological Structures

Skills develop through the hierarchical coordination of lower level action systems into higher order structures. Figure 1 presents the levels of hierarchical organization of a developing skill based on Fischer's dynamic skill theory (Fischer, 1980; Fischer and Bidell, 2006). Skills develop iteratively through four broad tiers: *Reflexes* consist of innate action elements (e.g., sucking a nipple placed in the mouth); *sensorimotor actions* refer to acquired actions directed toward objects (e.g., reaching for a seen ball). *Representations* consist of symbolic meanings about concrete aspects of the world (e.g., 'Eating candy is fun'); *abstractions* consist of higher order representations of intangible and generalized aspects of the world (e.g., "Conservation is the idea that the quality of something remains the same despite a change in appearance"). Within each broad tier, skills develop through four levels: A single *set* refers to a single organized reflex, action, representation, or abstraction. *Mappings* refer to coordinations between two or more sets, whereas *systems* consist of coordinations of two or more mappings. A *system of systems* arises from the intercoordination of at least two systems and is the equivalent of the first level of the next broad tier of skills. For example, a *system of sensorimotor systems* creates a single *representational set*. Dynamic skill theory identifies four broad qualitatively distinct tiers comprising a total of 13 specific levels.

Figure 3 The web of development.

Development in Infancy

Development in infancy spans two broad developmental tiers – reflexes and sensorimotor actions (*see* Motor Skills: Development in Infancy and Early Childhood). Reaching for objects is an example of a sensorimotor action. After a series of levels of prereaching develop during the reflex tier, beginning at around 15–17 weeks of age, infants enter the sensorimotor tier of development. As a result, they gain the capacity to construct single *sensorimotor actions*. Sensorimotor actions consist of controlled actions on objects in the environment. Using sensorimotor actions, in high support contexts, an infant can produce the first successful reaches

toward objects. When posture is supported, an infant can direct arm movements toward a seen object, grasp a toy placed near her hands, or move a grasped toy toward her mouth. Such single sensorimotor acts are represented as follows (see below figure).

Beginning around 7–8 months of age, infants gain the capacity to bring together two sensorimotor acts into a sensorimotor mapping. At this level, an infant is able to fully coordinate distinct acts of looking and reaching into a seamless action. In so doing, an infant can *reach* for an object to *grasp* it, or reach for an object in order to look at it (see below figure).

At this level, infants can reroute their reaches around barriers placed between themselves and target objects. If an adult tries to block a child's reach, he can redirect the reach around the obstacle. Beginning around 11–12 months of age, infants are able to coordinate two sensorimotor mappings into a *sensorimotor system* (S3). In so doing, infants can coordinate multiple acts of looking and reaching in order to explore an object from a variety of angles. Such coordinations are the equivalent of Piaget's concept of tertiary circular reaction (see below figure).

Development through the Representational Tier

Beginning around 18–24 months of age, children gain the capacity to coordinate two sensorimotor systems into a *system of sensorimotor systems*, which is the equivalent of the first level of the next tier of development – *single representational sets*. Using single representations, children form symbolic meanings in the absence of their referents. For example, using single representations, a child can pretend that a teddy bear can walk. In so doing, a toddler can use one sensorimotor system of actions (e.g., holding and moving the teddy bear) to regulate a second such system (e.g., making the bear move forward) in order to represent the symbolic act of walking (see below figure).

Single representations take different forms in many different modalities (e.g., pretend play, imagery, word use). Single representations are the rough equivalents of a single declarative sentence. Beginning around 3 ½ to 4 years of age, children gain the capacity to coordinate two single representations into a *representational mapping*. At this level, children begin to represent different relations between ideas (e.g., cause/effect; before/after; bigger/smaller; part/whole; reciprocity, and so forth). For example, children can compare the *relative height* of liquid poured into two glasses or the relative width of liquid poured into two glasses, but cannot keep both in mind simultaneously. Given a tall thin glass and a short wide glass filled with the same amount of liquid, a child can correctly indicate that the liquid in one glass is higher or wider than the other (see below figure).

By 6–7 years of age, children can begin to coordinate two representational mappings into a seamless *representational system*. At this level, a child can hold in mind a relationship between two relationships. In the traditional Piagetian conservation task, children are able to relate one representational mapping for comparing changes in height from tall to short to another mapping connecting changes from in width from thin to wide (see below figure).

Using this structure, children solve the conservation task by understanding that the amount of liquid remains the same in both glasses because changes in the height of the liquid in the glasses are compensated for by changes in width.

Developing through the Abstract Tier

Throughout the representational tier, a child's thinking remains concrete. Beginning around 10–11 years of age, in high support contexts, preteens gain the capacity to abstract what is common across multiple representational systems and coordinate them into a single abstraction. Using a single abstraction, a youth can represent intangible aspects of a single idea free from concrete content. For example, a teen can generalize across commonalities between conservation of mass and conservation of volume tasks to construct an abstract (content free) understanding of *conservation*: Despite a change in appearance, the quality of a phenomenon remains the same (see below figure).

Abstractions develop through the same iterative process that occurred in previous tiers (*see* Self-Regulation during

Adolescence: Variations Associated with Individual ↔ Context Relations*). Around 14–15 years of age, using *abstract mappings*, a teen can hold in mind the relationship between two abstractions. For example, a teen can represent the concept of conservation in terms of the inverse relationship between the loss of *kinetic energy* is lost (e.g., the slowing of the velocity of a ball thrown into the air) and the gain in *potential energy* (gravitational potential) (see below figure).

Using abstract systems, 17- to 18-year-olds begin to coordinate two abstract mappings into an abstract system. At this point, for example, a youth can represent relationships between two abstract aspects of one concept and two abstract aspects of another. One can, for example, represent the concept that *matter can neither be created nor destroyed* in terms of Einstein's principle relating the abstract concepts of *energy* and *matter* ($e = mc^2$) (see below figure).

The final level of skills emerges in early adulthood with the capacity to coordinate two or more abstract systems into *abstract principles* – highly abstract representations that organize multiple abstract ideas and large bodies of knowledge. Such skills only arise in individuals with extensive experience in particular domains of activity (e.g., advance training in a discipline).

Recent Advances: The Dynamic Self-organization of Integrative Psychological Structures

Epigenesis refers to the idea that psychological and behavioral structures emerge in development as a product of dynamic coactions between genes and a series of nested environments. Genes and environment are inseparable as causal processes in development. Although Piaget's equilibration model is an epigenetic one, the role he assigned to the environment was rather limited. In postulating a universal stage sequence, Piaget did not allow that schemes could develop in significantly different ways in different sociocultural contexts. According to contemporary epigenetic systems models of development, different developmental pathways self-organize as a product the interplay among diverse aspects of the person–environment system over time (Gottlieb, 2002; van Geert, 2000). One such model of the person–environment system is displayed in the top panel of **Figure 4** (Mascolo and Fischer, 2015). In this model, psychological structures are the emergent product of coactions that occur among systems that operate both within and between individuals. The integrative organization of individual action is indicated in the left panel of **Figure 4**. In any given context, (1) nonconscious *appraisals* of one's relation to one's environs (e.g., judgments of danger, goal blockage) generate (2) *emotional feelings* (e.g., fear, frustration) and (3) *action tendencies* (flee, fight). Thereupon, emotional feelings (4) provide feedback that *amplifies* the importance of appraised events and *selects* them for (5) conscious awareness within working memory. In this way, psychological structures that operate in working memory arise from the interplay of nonconscious cognitive and emotional processes (*see* Emotion in Cognition; Emotions, Psychological Structure of). Thus, although psychological structures regulate action, they do not do so autonomously; they self-organize as a product of the dynamic interplay among processes that operate both within and between individuals (*see* Language Development: Emergentist Theories).

To illustrate the emergent self-organization of psychological structures in real time, consider two brothers engaged in parallel play. After B referred to L as his 'little brother,' the following interaction occurred:

L: (Playing) No. I'm not a *little* brother. I'm big.
B: (Gently) I know you're not little, but (in a slightly sing-song 'teaching' voice) you're. When someone is younger than another brother, they call that a little brother.
L: Oh. (Slightly whining) I'm not (with rising intonation) *little* (looks toward O).

The bottom panel of **Figure 4** shows the emergent structure of thinking, feeling, and acting as it operated both *within* and *between* the two brothers. The left and right panels identify the structure of B's and L's activity, respectively. For each boy, the diagram identifies (1) the *appraisal* that organized affective and cognitive activity, (2) the *emotional expressions* produced by the appraisal, and (3) the structure of the child's *skilled action*. The symbol between the two panels identifies the ways in which the boys adjusted their behavior in relation to each other. In this situation, the little brother's slightly sad complaint that "I'm not little; I'm big" operated at the level of *representational mappings* (Fischer's, 1980). Responding empathically to the little boy's plea, the big brother modified the affective quality of his action, and, operating at the level of *representational systems*, attempted to console his brother. As indicated in this example, psychological structures are not isolated cognitive systems encapsulated within discrete individuals. Instead, they are integrative structures of thinking, feeling, and action that self-organize as interlocutors adjust their processes to each other over time.

Psychological Structures Are Dynamic Constructions

Psychological structures self-organize in both real and developmental time. To say that they self-organize implies that there is no single, fixed or isolated genetic, psychological or sociocultural plan that directs the course of development. The pathways of development are neither fixed nor predetermined. Instead, they emerge over time as a product of richly interactive person–environment interactions. Novel skills coevolve with the formation of novel forms of cultural life. Rather than thinking of development in terms of fixed

Figure 4 The joint construction integrative structures of action.

pathways, it is better to think of developmental pathways themselves as emergent outcomes. That is, while we sometimes walk along pathways that have already been paved for us, in development, we typically forge our own unique paths as we walk.

Neo-Vygotskian Developmental Theory

Yuriy V Karpov, Touro College, New York, NY, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Lev Vygotsky's Russian followers have elaborated his ideas into an innovative developmental theory, in which each period in children's development is characterized by their leading activity. In the context of this activity, adults mediate children's mastery of new psychological tools, which results in the development of new mental processes in children. As another outcome of adult mediation, children develop a new motive. As a result, children transit to the new leading activity that is specific to their next age period. Vygotsky's followers have used this theoretical model to analyze children's development in industrialized societies from birth through adolescence.

After Lev Vygotsky's premature death in 1934 at the age of 37 years, his sociocultural developmental theory became the general theoretical foundation for the scientific research and discourse of his Russian colleagues and followers (Daniil Elkonin, Piotr Galperin, Alexei Leontiev, Alexander Luria, Alexander Zaporozhets, and others). They, however, were far from considering Vygotsky's theory a dogma; rather, their scientific efforts were aimed at overcoming the shortcomings of Vygotsky's theory and elaborating those of his ideas that were just sketched by Vygotsky.

Neo-Vygotskian Theoretical Ideas

In their scientific discourse, the neo-Vygotskians repeated all the major steps that Vygotsky undertook when developing his theory. At each step, however, they refined and elaborated the original ideas of Vygotsky.

Psychological Tools

The key idea of Lev Vygotsky's theory is his analogy between practical and mental activities of humans. He held that the major characteristic of human mental processes is that they, just like human labor, are mediated by tools. But, these are special, psychological tools such as language, concepts, signs, and symbols. Humans are not born with these tools, just as they are not born with tools of labor; rather, these tools reflect the accumulated experience of human kind that children acquire and master. Having been mastered by children, psychological tools come to mediate their mental processes. Specifically, human mental processes that are mediated by tools were called by Vygotsky higher mental processes to distinguish them from lower mental processes, with which children are born, and which are specific to both young children and animals.

Having appropriated from Vygotsky the notion of psychological tools as mediators of human mental processes, his Russian followers, however, have considerably elaborated upon this notion. For Vygotsky, psychological tools were semiotic tools (language, concepts, signs, and symbols). Vygotsky, to be sure, realized that a child's learning a new word, concept, sign, or symbol does not automatically make this word, concept, sign, or symbol a psychological tool that comes to mediate this child's mental processes. Discussing, for example, scientific concepts as psychological tools that come to mediate mental processes of school-aged children, Vygotsky (1934/1986) noted that "the difficulty with scientific concepts lies in their *verbalism*" (p. 148). He also pointed out that "scientific concepts … just start their development, rather than finish it, at a moment when the child learns the term or word-meaning denoting the new concept" (Vygotsky, 1934/1986: p. 159). Vygotsky, however, never elaborated these reservations. Therefore, his theory is traditionally (and, in general, correctly) associated with the notion of semiotic tools as mediators of human mental processes (see, e.g., Kozulin, 1986).

Could, however, words, concepts, signs, or symbols by themselves serve as psychological tools mediating human mental processes? From Vygotsky's (1981) perspective, a sign "alters the entire flow and structure of mental functions. It does this by determining the structure of a new instrumental act, just as a technical tool alters the process of a natural adaptation by determining the form of labor operations" (p. 137). The point is, however, that a practical (or technical) tool by itself does not determine the form or structure of a human operation, since the possession of a tool does not lead automatically to the mastery of the procedure for the use of this tool. For example, mere giving chopsticks to one who never used them before will not make it possible for him to use them. The procedure for the use of this tool as a tool for eating will still be missing. Similarly, giving a spoon to an infant does not change the structure of his or her manual operation, and it is not sufficient for the use of this tool in the right way. To use the spoon as a tool for eating, the infant should master the procedure for the use of this tool. Therefore, "the mastery of a tool does not simply mean the possession of the tool, but it means the mastery of the procedure for the use of this tool" (Leontiev, 1959: p. 213).

The same is true of psychological tools. The mastery of a psychological tool requires that the child has mastered the procedure for the use of this tool (Galperin, 1969; Leontiev, 1959, 1983). As Leontiev (1983) indicated, "In order for a child to develop the highest generalization (a concept), it is necessary to develop in him the system of psychological operations [procedures – Y.K.] that are relevant to this highest generalization" (p. 347). Thus, the acquisition of Archimedes' law or the concept of perpendicular lines implies not only that

students are able to repeat this law or concept, but that they have also mastered the procedures that make it possible for them to apply this law or concept to solve subject-domain problems. The elaboration by Vygotsky's followers of his notion of psychological tools has been especially important for the development by them of an innovative approach to instruction, which will be discussed below.

Internalization of Psychological Tools

In Lev Vygotsky's writings, a major aspect of mastery of a psychological tool is its internalization, which, in line with his view of the nature of psychological tools, he understood as "the ingrowing of signs into the individual mental processes" (Arievitch and Van der Veer, 1995: p. 114). For example, from Vygotsky's perspective, a major phenomenon in memory development takes place when "the external sign (e.g., a string tied around the finger – Y.K.) that school children require has been transformed into an internal sign produced by the adult as a means of remembering" (Vygotsky, 1978: p. 45).

From the neo-Vygotskians' perspective, as discussed, the mastery of a psychological tool requires that the child has mastered the procedure for the use of this tool. Therefore, in their view, internalization of a psychological tool involves the internalization of the procedure of the use of this tool. As Alexei Leontiev (1959) wrote, "The mastery of mental procedures, which underlies the acquisition by an individual of knowledge and concepts accumulated by human kind, necessarily requires the transition from the performance of external procedures to … gradual internalization of the procedures, which results in their transformation into abridged mental procedures" (p. 305). Thus, in case of memory development, the difference between school children and adults is not that, as Vygotsky held, in order to memorize and recall, children use external signs, and adults use internal signs. Rather, the difference is in the level of internalization of their mnemonic procedures. The mnemonic procedures of school children are partially exteriorized and therefore cannot be performed without an external support (such as a string tied around the finger), whereas adults can use internal mnemonics.

Mediation as the Determinant of Mental Development

In contrast to Jean Piaget, who believed that children develop new mental processes as a result of independent exploration of the environment, Lev Vygotsky held that, being products of human culture, psychological tools should be explicitly taught to children by representatives of this culture. The process of teaching children psychological tools has been called mediation. In the course of mediation, an adult presents to the child a new psychological tool in the form of an external device and monitors the child's appropriation and mastery of this tool. As the child increasingly masters the tool, it gets internalized and turns into an internal mediator of the child's mental process. Simultaneously, the adult is getting less and less involved in monitoring the child's mastery of this tool. As a result, the child transits from the use of the external psychological tool as mediated by the adult, to the independent use of the internal psychological tool, which indicates the completion of the development of a new higher mental process.

Having enthusiastically adopted Vygotsky's general notion of mediation as the major determinant of mental development, the neo-Vygotskians have significantly elaborated on Vygotsky's understanding of the nature of mediation. Vygotsky's view on psychological tools as semiotic tools determined his understanding of the process of mediation as child–adult verbal communication. As Alexei Leontiev and Alexander Luria characterized Vygotsky's view on mediation, it leads to the position that "whatever is of major importance for the development of individual consciousness, is introduced into it through social consciousness" (Leontiev and Luria, 1968: p. 353).

For the neo-Vygotskians, as noted, the mastery of a psychological tool requires that the child has mastered the procedure for the use of this tool. But, whereas, for example, Archimedes' law can be taught to children via verbal communication, the procedures for application of this law to solve subject-domain problems cannot be just verbally described. Rather, these procedures have to be modeled by an adult and taught to children, and then mastered and internalized by children in the course of their use in problem solving under adult guidance. Therefore, for the neo-Vygotskians, mediation has to take place in the context of child–adult joint activity.

Motivational Factors in Child Development

Stressing mediation as the major determinant of development, Lev Vygotsky was far from viewing children as passive recipients of adult mediation. Discussing, for example, school instruction, which he considered to be the major avenue for mediation during the period of middle childhood, Vygotsky (1984/1998) indicated that "children … never learn without interest" (p. 24). Thus, according to Vygotsky, children's motivation is a necessary prerequisite for their engagement in mediational interactions with adults. As children transit from one developmental stage to the next, they have to become engaged in new mediational interactions, which requires that they have developed new motives. The development of new motives, according to Vygotsky "is the content of the social-cultural development of the child to a much greater degree than of his biological formation" (1984/1998: p. 11). He never elaborated this contention; since, however, Vygotsky viewed the social-cultural development of the child as an outcome of mediation, it can be assumed that he considered mediation to be mainly responsible for the development of new motives in children.

For the neo-Vygotskians, who stress the role of child–adult joint activity as the major avenue for mediation, the problem of children's motivation has become of even greater importance than it was for Vygotsky. Indeed, "there can be no activity without a motive"; a motive serves as "an activity's object that gives it a specific direction" (Leontiev, 1972/1981: p. 59). Therefore, it is the development of a new motive that propels the child to become engaged in a new activity.

Discussing the mechanism of the development of new motives in children, the neo-Vygotskians describe it as the process of ripening of a new motive within the context of a current activity (Leontiev, 1959). For example, if a person is engaged in job-related learning in order to improve his job

performance, his learning is driven by a motive of successful job performance rather than by learning motivation. It may happen, however, that this person at a certain point develops a strong intrinsic interest in learning within a certain domain. Then, the new learning motive will propel this person to become engaged in a new activity (e.g., to enroll in a college program).

In the above example, the ripening of a new motive has happened spontaneously. The neo-Vygotskians hold, however, that adults, rather than relying on the chance of spontaneous formation of new motives in children, should actively mediate this process in the context of their joint activities with children (Elkonin, 1971/1972, 1989; Leontiev, 1959, 1972/1981; Zaporozhets, 1978/1997; Zaporozhets and Elkonin, 1964/1971).

The Notion of a Leading Activity as the Cornerstone of the Neo-Vygotskian Model of Child Development

The term leading activity was initially used by Lev Vygotsky in reference to preschoolers' play as leading their development in this age period (1966/1976: p. 537). For him, however, this term was a figure of speech rather than a well-defined concept. To characterize different periods in children's development, Vygotsky preferred to use the term "the social situation of development," which he vaguely defined as a "unique relation, specific to the given age, between the child and reality, mainly the social reality, that surrounds him" (1984/1998: p. 198). It is in the context of the present social situation of development that, according to Vygotsky, adults engage children in age-specific mediational interactions. As a result, children develop new motives and new mental processes, which leads to their transition to the next social situation of development, that is, to the next developmental period.

For the neo-Vygotskians, who stress the role of children's activity as mediated by adults in their development, it has been a logical move to abandon Vygotsky's vague term "social situation of development" and to adopt instead the notion of a leading activity. Introducing this notion, Alexei Leontiev (1959) suggested that among different activities in which children are engaged in a given age period, there is one activity, the leading one, which plays the major role in children's development during this age period and prepares them for the transition to the next age period. What activity is leading in the given age period is crucially determined by the society in which children live. For example, in industrialized societies, in which children are required to learn in educational settings during the period of middle childhood, the leading activity of preschoolers would be the one that results by the end of preschool period in the development of children's school readiness. Sociodramatic play, according to Leontiev, meets this requirement the best. Therefore, sociodramatic play is the leading activity of preschool children in industrialized societies.

The notion of a leading activity has been enthusiastically embraced by Daniil Elkonin, Alexander Zaporozhets, and other neo-Vygotskians, and it has become the cornerstone of their theoretical model of child development (Elkonin, 1971/1972, 1989; Zaporozhets, 1978/1997; Zaporozhets and Elkonin, 1964/1971), which can be presented as follows. In each age period, children are engaged in the leading activity, which is driven by their leading motive (i.e., the most important one among all their motives in this age period). The children's present mental processes are not sufficient for their independent performance of this activity; therefore, this activity is performed as joint child–adult activity. In the context of this activity, adults mediate children's mastery of new psychological tools, which results in the development of new mental processes in children. As another outcome of adult mediation, children develop a new strong motive, which becomes their new leading motive. As a result, children transit to the new leading activity, which is specific to their next age period.

Neo-Vygotskian Analysis of Developmental Periods

The above-described theoretical model has been used by the neo-Vygotskians to analyze developmental periods in industrialized societies and to explain the mechanism of children's transition from one developmental period to the next.

First Year of Life: Emotional Interactions with Caregivers as the Leading Activity of Infants

In discussing the first year of life, Lev Vygotsky (1984/1998) emphasized infants' 'biological helplessness' (p. 215), inability to satisfy their vital physiological needs by themselves, which results in their dependence on adults. This dependence, according to Vygotsky, becomes the basis for the development of infants' emotional ties to caregivers (in contemporary psychology, these ties are often referred to as attachment).

Having embraced the aforementioned ideas, the neo-Vygotskians, at the same time, argue that infants' attachment to caregivers is not a direct and necessary outcome of the gratification of their physiological needs, as Vygotsky (1984/1998) was inclined to believe. Rather, the formation of attachment is the result of emotional interactions, in which caregivers engage infants in the context of gratification of their physiological needs by smiling at them, talking to them, and fondling them. As a result, infants, initially not responsive to these adult efforts, gradually start, first, to respond to adult initiations of emotional interactions, and then, to initiate these interactions themselves by smiling, vocalizing, and using body gestures. Infants' taking initiative in the emotional interactions with caregivers indicates that they have developed a new motive, which comes to drive their new activity of emotional interactions with caregivers. This activity, according to the neo-Vygotskians, becomes infants' leading activity during the first year of their lives, because it results in the major developmental accomplishments of this period, with attachment being the most important of them (Elagina, 1977; Elkonin, 1971/1972, 1989; Lisina, 1986; Zaporozhets and Lisina, 1974). The other developmental accomplishments (many of which are built upon attachment) are as follows.

First, infants' affection to caregivers is 'transferred' to toys and objects that caregivers present to them in the context of emotional interactions with encouragement to manipulate these objects. As a result, infants develop interest in object-centered explorations, which, by the end of the first year,

becomes much stronger than their interest in emotional interactions with adults and turns into infants' new leading motive.

Second, attachment results in the 'acceptance' of caregivers by infants as mediators of their relations with the external world. In particular, this 'acceptance' reveals itself in infants' using primary caregivers as the 'reference point' in an uncertain situation, as well as in their actively seeking for caregivers' help with new objects and toys by the end of the first year.

Third, the advancement of infants' object-centered explorations increases their need for caregivers' help with new objects and toys, which requires that they develop means of communication with caregivers. Accordingly, infants willingly acquire the means of gestural communication that caregivers model for them. The most important of them, the pointing gesture, in addition to its communicative value, becomes the foundation for later language development and the development of self-regulation in children.

Thus, by the end of the first year of life, as a result of adult mediation, infants develop all the prerequisites for their transition to the next age period, in which object-centered joint activity with adults becomes their new leading activity.

Second and Third Years of Life: Object-Centered Joint Activity with Adults as the Leading Activity of Toddlers

To be sure, toddlers learn much about the physical world through independent explorations, such as shaking and throwing objects, pushing small objects into different holes, and so on. However, since these explorations do not require adult assistance, they do not create a context for adult mediation. Therefore, the neo-Vygotskians give major importance to toddlers' actions with social objects, including their play with toys. As opposed to physical characteristics of objects, their social meanings are not 'written' (Elkonin, 1989: p. 48) on objects and, therefore, cannot be discovered by children independently. Thus, children's learning how to use social objects (e.g., how to use a spoon to eat rather than banging it on the table) can take place only within child–adult joint activity, which provides adults with a context for mediation. That is why the neo-Vygotskians hold that object-centered joint activity with adults becomes the leading activity of toddlers during the second and third years (Elkonin, 1978, 1989; Zaporozhets and Lisina, 1974).

Discussing the advancement of children's object-centered activity, the neo-Vygotskians stress the role of adults who introduce new objects and toys to children and model their proper use (Bugrimenko and Smirnova, 1994; Elkonin, 1978). The neo-Vygotskians especially stress the fact that it is adults who initially introduce object substitutes to children and teach them how to use these substitutes in play (e.g., by suggesting to the child to use a stick as a substitute for a spoon when feeding a doll), which marks children's transition from realistic to symbolic play.

The developmental outcomes of object-centered joint activity (which make this activity the leading one in this age period) are as follows. First, as this activity advances, it comes to require that children develop more sophisticated means of communication with adults than, for example, a pointing gesture. As a result, children, with caregiver guidance and encouragement, acquire language remarkably fast (Elkonin, 1989; Lisina, 1986). This is especially important since language is not only the major tool for social communication, but it is also a psychological tool that comes to mediate children's mental processes. In particular, children become capable of self-regulation by the use of private (self-directed) speech (Luria, 1961).

Second, the use of object substitutes (which represents "a vital transitional stage to operating with meanings" (Vygotsky, 1966/1976: p. 548)), and the acquisition of language (which, in particular, makes it possible for children to rename object substitutes for missing objects) promotes the development in children of symbolic thought (Elkonin, 1978).

Third, with adult help, children discover the exiting world of social roles and relationships that is 'hidden' under the world of social objects (Elkonin, 1978, 1989; Leontiev, 1959). As a result, the imitation of social roles and relationships becomes children's new strong motive (e.g., when playing a mother–daughter game, a 2-year-old girl will imitate the action of feeding a doll with a spoon, whereas a 3-year-old girl will imitate mother–daughter relationships, such as love, care, etc.)

Thus, by the end of the third year, as a result of adult mediation, children develop all the prerequisites for their transition to the next age period, in which sociodramatic play becomes their new leading activity.

Three- to Six-Year-Olds: Sociodramatic Play as the Leading Activity during the Period of Early Childhood

The Vygotskian view on sociodramatic play (which is interchangeably referred to as 'play' in this section) is just the opposite of the common belief that play is children's free spontaneous activity in which they do whatever they want, liberating themselves from any rules and social pressure (Vygotsky, 1966/1976; Elkonin, 1978, 1989; Leontiev, 1959; Zaporozhets, 1978/1997). Rather, following Lev Vygotsky, the neo-Vygotskians hold that by the age of 3 years children develop a strong interest in the world of social roles and relations; that is why they start to imitate and explore these roles and relations in play. Adults facilitate and promote sociodramatic play by presenting and explaining different social roles to children. Such mediation of sociodramatic play by adults is especially important since play leads to major developmental outcomes of this age period.

First of all, in play, the child "looks at himself from the point of view of the role he has taken … and discovers that he is not an adult yet" (Elkonin, 1978: p. 277). Thus, in play children come to realize that, in order to become adults, they should study at school rather than playing adults. As a result, by the age of 6 years, children develop learning motivation as their new leading motive (it is important to note that, although this neo-Vygotskian assumption has been supported by observations (Bozhovich, 1968), it is still lacking strong empirical support).

Second, Vygotsky (1966/1976) and his followers (Elkonin, 1978; Leontiev, 1959) emphasize that, contrary to 'common wisdom,' children are not free in play. In play, children are supposed to act in accordance with their roles, and all playmates are strictly monitoring each other's proper following of his or her play role. But, each role contains some implicit rules; a rule "is hidden … under the role" (Elkonin, 1978: p. 248). Thus, as

a result of mutual monitoring in the context of their play, children learn to suppress their impulsivity and to follow rules, that is, develop the ability to self-regulate their behavior.

Third, in play, children overcome their cognitive egocentrism, that is, inability to take into consideration the position of another person, or to look at a certain event from different perspectives. Indeed, play requires that children coordinate their play actions with the play actions of their playmates; therefore, in play the child's "ability to coordinate his point of view with other possible points of view develops" (Elkonin, 1978: p. 282).

Finally, in the course of sociodramatic play, children use object substitutes and perform within an imaginary situation (develop the plot of the game, plan their play actions, etc.), which further promote the development of their symbolic thought (Elkonin, 1978; Vygotsky, 1966/1976).

The neo-Vygotskians hold that the above developmental accomplishments are crucially important for children's successful learning at school (Bozhovich, 1968; Elkonin, 1978; Leontiev, 1959). Thus, in the course of sociodramatic play, children develop the major components of school readiness, which is a necessary prerequisite for their transition to learning at school as their new leading activity during the period of middle childhood.

The Period of Middle Childhood: Learning at School as Children's Leading Activity

According to Lev Vygotsky (1978, 1934/1986), school instruction is the major avenue for mediation and, therefore, the major contributor to children's development during the period of middle childhood. He emphasized, however, that such a developmental effect will take place only if instruction is organized in the proper way: "The only good kind of instruction is that which marches ahead of development and leads it" (Vygotsky, 1934/1986: p. 188). The major reason for developmental outcomes of school instruction relates to students' acquisition of scientific concepts, which, having been acquired and internalized, become the tools of children's thinking and problem solving; "instruction in scientific concepts plays a decisive role in the child's mental development" (Vygotsky, 1982/1987: p. 220). Specifically, "reflective consciousness comes to the child through the portals of scientific concepts" (Vygotsky, 1934/1986: p. 171). As a result, students' thinking becomes much more independent of their personal experience, and they become capable of exercising formal-logical thought (Luria, 1974/1976; Tulviste, 1991).

The neo-Vygotskians have embraced the aforementioned ideas of Vygotsky and have characterized learning in educational settings as the leading activity of children in industrialized societies during the period of middle childhood; they, however, substantially elaborated Vygotsky's views of school instruction (Davydov, 1972/1990, 1999; Elkonin, 1989; Galperin, 1974/1989; Leontiev, 1959; Talyzina, 1975/1981). As already noted, the neo-Vygotskians repudiated the vision of 'good' instruction as providing children with scientific concepts in the course of verbal communication (the position to which Vygotsky's writings sometimes could lead); rather, they argue, students should be presented with a combination of scientific concepts and relevant procedures. Neo-Vygotskian studies have demonstrated that the procedures that underlie the major subject-domain concepts are methods for scientific analysis in a given subject domain. For example, the procedures that underlie Archimedes' law are the methods of calculating the density of different objects and comparing these densities with the density of water. Similarly, the procedures that underlie the concept of perpendicular lines are the methods of identifying within a given pair of lines those attributes that are necessary and sufficient for associating (or not associating) this pair of lines with the concept of perpendicular lines. The mastery and internalization of scientific concepts and procedures by students should take place in the course of their use of this knowledge under teacher guidance for solving subject-domain problems. The implementation by the neo-Vygotskians of these ideas in educational practices has become known as the theoretical learning approach to instruction.

As evaluation studies have demonstrated, the use of theoretical learning improves dramatically both the learning and developmental outcomes of school instruction (for reviews in English, see Arievitch and Stetsenko, 2000; Davydov, 1972/1990; Talyzina, 1975/1981). One of its major developmental outcomes relates to the facilitation of the development of formal-logical thought in students to a much greater extent than happens under 'traditional' instruction. These findings are especially important since, as will be discussed in the next section, formal-logical thought is a necessary prerequisite for children's transition to the next period of development, that is, the period of adolescence.

The Period of Adolescence: Interactions with Peers as the Leading Activity of Adolescents

According to Lev Vygotsky (1984/1998), the change of adolescents' interests is "the key to the whole problem of the psychological development of the adolescent" (p. 3). This change not only has its roots in physiological (especially, sexual) maturation, but also "there is a reconstruction and formation of interests from the top, from the aspect of the maturing personality and the world view of the adolescent" (Vygotsky, 1984/1998: p. 23). As for the development of adolescents' 'personality and world view,' it becomes possible because of their transition to formal-logical thought; as Vygotsky (1984/1998) noted, "an adolescent appears before us primarily as a thinking being" (p. 30). Because of the new ability to do formal-logical thought, "a whole world with its past and future, nature, history, and human life opens before the adolescent" (Vygotsky, 1984/1998: p. 42). Formal-logical thought also makes adolescents capable of self-analysis, the analysis of their feelings, and their place in the world. The tools for such analysis are social norms and values, which are provided to adolescents by the society; therefore, in Vygotsky's (1984/1998) words, "self-consciousness is social consciousness transferred within" (p. 182).

According to Russian followers of Vygotsky, the major shortcoming of his view of adolescence was overlooking of the role of adolescents' activity in their development. Applying the concept of leading activity to the analysis of adolescence, the neo-Vygotskians suggested that interaction with peers is the leading activity during this period (Elkonin, 1971/1972). To regulate their interactions within a peer group, adolescents use

social norms and values, which they have appropriated from their caregivers, as standards for the behavior of their peers, as well as reflect on their peers' use of social norms and values as standards for their own behavior (Bozhovich, 1968; Elkonin, 1989). As a result, they test, master, and internalize these norms and values, which leads to the development of their self-consciousness (or personal identity, in Erikson's terms) – the major accomplishment of this period that prepares adolescents for the transition to adulthood.

The strongest point of the neo-Vygotskians' explanation of adolescence is that they repudiated the vision of an adolescent as a passive recipient of social norms and values, or as a 'theorist' who suddenly becomes interested in the development of self-consciousness – the vision to which some of Vygotsky's writings may lead. In the neo-Vygotskian theoretical model, the major developmental accomplishments of adolescence (just as the major developmental accomplishments in other periods) take place only because they are required by the activity that is leading during this period.

The major flaw in the neo-Vygotskians' view of adolescence is that they have not answered the question, what motive propels adolescents to become engaged in interactions with peers? A possible answer to this question can be drawn from Vygotsky's idea (abandoned by his Russian followers) that sexual maturation lies "at the base of the whole change in the system of interests in the adolescent" (1984/1998: p. 16). Indeed, there is some evidence that it is sexual motives that propel adolescents to become engaged in interactions with peers (Cole and Cole, 2001: p. 626).

Neo-Vygotskian Developmental Theory: Accomplishments and Shortcomings

Russian followers of Vygotsky have elaborated his theoretical ideas into a logical and internally consistent theory that integrates cognitive, motivational, and social aspects of child development, while successfully overcoming the limitations of Vygotsky's theory. In their theory, adult mediation in the context of children's leading activity results in their cognitive and motivational development, which, in turn, results in their transition to the new leading activity that is specific to the next period of development. Thus, the neo-Vygotskians have achieved the goal that Vygotsky formulated but fell short of reaching; they have presented the process of child development as "a single process of self-development" (1984/1998: p. 189).

To avoid possible misunderstandings of neo-Vygotskian developmental theory, it is important to make two reservations. First, the leading activities described by the neo-Vygotskians are those that are specific for children in industrialized societies. In preliterate societies, neither sociodramatic play is the leading activity during the period of early childhood (Elkonin, 1978), nor is learning in educational settings the leading activity during the period of middle childhood. Second, even in industrialized societies, children may not be engaged in the activity that is leading in a given period; this, however, will result in serious developmental problems. For example, contemporary preschoolers are not much engaged in sociodramatic play, which has been shown to result, in particular, in very poor quality of their self-regulation (Bodrova and Leong, 2006).

Although the neo-Vygotskians' developmental theory has found strong empirical support in the studies of contemporary researchers, some of their notions can be disputed. Their most disputable notion is a disregard of the role of physiological maturation in children's development; as discussed, this disregard, in particular, has weakened the neo-Vygotskian analysis of adolescence.

Network Analysis

Antonio M Chiesi, Università degli Studi di Milano, Milano, Italy

Abstract

Network analysis can be regarded as a set of techniques with a shared methodological perspective, which allow researchers to depict relations among actors and to analyze the social structures that emerge from the recurrence of these relations. The basic assumption is that better explanations of social phenomena are yielded by analysis of the relations among entities. This analysis is conducted by collecting relational data organized in matrix form. If actors are depicted as nodes, and their relations as lines among pairs of nodes, the concept of social network changes from being a metaphor to an operative analytical tool that utilizes the mathematical language of graph theory and linear assumptions of matrix algebra.

The Network Approach in Social Sciences

The notion that social phenomena can be interpreted as networks of relations, that society itself can be viewed as a web, and that social action can be seen as the outcome of constraints and opportunities emerging from interpersonal relations enjoys increasing consensus among social and behavioral scientists. The reasons for this success are in line with a view that fosters the use of the term 'network' as a metaphor for society: the diffusion of the Internet as an emblematic representation of globalization, the evolution of the economy into being based on increasingly open and flexible firms whose efficiency is related to their weblike structure, the emergence of a third sector based on informal relations as opposed to a declining welfare state.

In recent decades the success of relational approaches in the empirical social sciences has been undoubtedly supported by the rapid development of network analysis (NA) tools.

NA is a set of integrated techniques to depict relations between actors and to analyze social structures emerging from the recurrence of these relations. The basic assumption is that better explanations of social phenomena should be found in the analysis of the relations between entities, which is carried out through the collection of relational data organized in matrix form, rather than in their social characteristics, which are usually surveyed on a set of individuals sampled from a larger population.

Traditional sample surveys isolate each actor and reduce his or her social relations to individual characteristics, in order to analyze statistical relations between variables. These causal relations can be only interpreted as useful indicators of underlying mechanisms, which are in fact any kind of encounters and exchanges between real actors who display their everyday life strategies.

NA concentrates its analytical attention directly on these phenomenological encounters, while traditional surveys can only identify causal connections without explaining effective operating mechanisms. For instance, a statistical relation between social origin and status attainment can in no way depict the actual mechanism of social mobility; it is only a signal of social relations both among relatives and within the larger social milieu of the respondent. The shape and intensity of the network of these relations constitute the explanation of the persistence or changes of social status through generations. Although deterministic approaches usually emphasize the point that NA enables a study of how the social structure of relationships around a person, group, or organization affects behaviors and attitudes, social networks are in turn constructed by individual or corporate actors, to the extent that they can mobilize social resources to choose partners or counterparts and to organize coalitions. In short, structurally bounded purposive actions can interplay with social structure, and vice versa.

If actors are depicted as nodes and their relations as lines connecting pairs of nodes, the concept of social network changes from an evocative metaphor, as it has been for a long time since the beginning of the twentieth century, to an operative analytical tool that can take advantage of the mathematical language of graph theory and of matrix and relational algebra. Concepts and theorems of graph theory can be meaningfully applied to NA methods. Matrix algebra is a powerful tool for managing relational data, for measuring distances between nodes, and for computing centrality and centralization statistics (Wasserman and Faust, 1994).

Since the mid-1970s, the development of algorithms (which have subsequently been integrated in statistical packages) and the availability of greater computational capability in the decade that followed have enabled the successful application of these techniques to structures larger and more complex than the personal networks studied previously. (The best known and most widely used packages are Pajek, UCINET, and StOChastic NETworks (StOCNET). The last of these includes the SIENA program, which allows dynamic analysis of longitudinal network data. An extensive comparative analysis of 31 programs and software toolkits for NA is made available by Huisman and van Duijn in Carrington et al. (2005). Graphical techniques and visualization of networks programs are also presented and compared by Freeman in Carrington et al. (2005).) The foundation of specialized journals such as *Social Networks* and *Connections* and the publication of NA manuals in different languages (Scott, 1991; Wasserman and Faust, 1994; Degenne and Forsé, 1994; Chiesi, 1999) has helped to institutionalize this approach, so that NA now finds increasing acceptance in the literature of such disciplines as sociology, economics, anthropology, social psychology, history and political science, as well as communication science, and even

biology (application to animal behavior) and epidemiology (human immunodeficiency virus diffusion patterns), while statistics and mathematics contribute to the development of analytical tools. The activity of an interdisciplinary community of scholars is evidenced by the founding of the International Network for Social Network Analysis in the late 1970s.

These developments have induced some scholars, mostly structural analysts, to identify a new scientific paradigm. Indeed, NA has features typical of what Thomas Kuhn – in his well-known book on scientific revolutions – defined as a paradigm: the formation of a community of scholars who share a special language, publish journals, and meet regularly at conferences to discuss specialized topics concerning applications of technical tools and their theoretical interpretation. There is evidence of the cumulative nature of this activity, in spite of the heterogeneity of the disciplines involved and of its fields of application.

However, NA has long suffered from a lack of shared theoretical assumptions and of theories derived from these assumptions. The idea that society is itself a set of relations and that individual actors are embedded in social networks is still too loosely defined for it to become a theory. For these reasons, NA has been sometimes defined as a technique in search of a theory. One may accordingly regard it as a set of techniques with a shared methodological perspective, rather than a new paradigm in the social and behavioral sciences. These techniques make it possible to dismiss a metaphor and to undertake substantive research, which yields good descriptions of complex structures and generates theoretical interpretations of processes that imply exchanges, information flows, power relations, or social interpersonal support at individual level, as well as interorganizational relations of influence, coordination, and control.

Origins and Development

The straightforward idea that any relational phenomena can be interpreted as network structures, that society itself can be interpreted as a network, and that social action can be explained as the outcome of constraints imposed and the opportunities afforded by social relations has been recurrent since Simmel's formal sociology and his studies on the relations between actors in dyads and triads at the beginning of the twentieth century. Nevertheless, it is only since the 1930s that attempts have been made in various disciplines to move from theoretical programs to empirical applications (Scott, 1991).

The first approach, influenced by gestalt theory, was developed in the United States by a group of social psychologists who had emigrated to that country from Germany. Jacob Moreno, Kurt Lewin, and Fritz Heider stressed the role played by the structure of interpersonal relations in the construction of cognitive schemes, and they studied information flows and the formation of shared ideas. The main tool that they used for the description of empirical networks was the *sociogram* – nothing more than a graphic representation of links (the interpersonal relations) between nodes (the actors) – together with analytical concepts like symmetrical–asymmetrical relation, centrality and periphery, as well as reciprocity and cognitive balance.

Another approach is directly linked to structural functionalism and it was used to recast the classic research study on work organization in the wiring room of the Western Electric plant at Hawthorne by Fritz Roethlisberger and William Dickson during the 1930s. In that study, observation techniques drawn from anthropology had highlighted the importance of informal relations in work performance. Some years later, George Homans reorganized the same data in matrix form to conduct analysis very similar to what came to be called 'block model' in the 1970s.

The so-called Manchester School of Social Anthropology, whose main figures are Max Gluckman, John Barnes, Clyde Mitchell, and Elizabeth Bott, also started from structural functionalism. But in contrast to the traditional emphasis on social integration and cohesion, this school developed NA concepts to study conflict and power relations. Its shift of research subject from African communities to next-door neighbor relations in European cities led to the discovery of the importance of informal relations in urban settings. The Manchester School applied concepts like density, connectivity, and reachability as well as parameters related to the intensity and strength of ties, but its exclusive concern with informal relations and its merely descriptive approach have contributed to the decline of this school since the 1970s.

By this time the main technical developments had moved to Harvard, where Harrison White devised mathematical concepts of structural analysis, following the pioneering work of Frank Harary and Dorwin Cartwright during the 1950s. Thereafter, the mainstream program would be to model the formal properties of social structures on the basis of graph theory and matrix algebra. The approach was, therefore, analytical and deductive rather than descriptive and inductive. Different types of graphs representing networks were defined and their properties studied. Field research and applications generated statistical debate on centrality, centralization, and the identification of cliques and other types of subgroups, while important concepts such as 'structural equivalence' were proposed.

The main theoretical assumption that fostered these technical developments was structural analysis, which theorized that an actor's behavior and attitudes can be interpreted in terms of his or her structural position in the network. Since the end of the 1970s, however, this deterministic approach has been criticized, prompting a second generation of authors to investigate the structural opportunities available to actors when they use relations that can be mobilized from specific positions. In sociology especially, this reorientation has yielded results pertaining both to substantive theories and to analytical models, usefully employed to suggest explanations of social phenomena (Cook et al., 1983, for instance).

As regards the former of these domains, different analytical types of ties, as well as concepts such as point centrality, network centralization, and structural balance, have been proposed, together with numerous criteria for subgroup detection (*see* Social Network Models: Statistical). The concept of structural equivalence, introduced by Francis Lorrain and Harrison White in the 1970s, has been inspired directly by role theory.

Recent Results

As regards substantive research, a number of middle-range theories can be grouped into five different fields of empirical

applications, while a sixth interdisciplinary approach is specialized in the detection of common structural features of large networks.

Network Structure and Actor Behavior

The relation between network structure and actors' behaviors and attitudes has generated results demonstrating that the density of ego-centered networks is correlated with mental disorders (Kadushin, 1982), the efficiency of task-oriented groups depends on their structure (Bavelas, 1950), members of cohesive networks tend to share common opinions (Epstein, 1969), and innovation diffusion is influenced by personal relations between actors (Coleman et al., 1957, Valente in Carrington et al., 2005).

Networks and Social Inequalities

The role played by networks in preserving and creating social inequalities has been investigated by research on social mobility, where macro-outcomes at the level of social stratification and microstrategies are analyzed jointly by means of network techniques. Moreover, studies on the labor market have evidenced that people acquire information about job opportunities mainly from informal relations, and 'strong' or 'weak' interpersonal ties determine differential chances of entering employment according to the segmentation of the labor market based on skills (Granovetter, 1973; Grieco, 1987) or gender (Lin, 2004).

Networks and Economic Behavior

The function played by networks in economic behavior and market mechanisms has inspired studies of interlocking directorates (Stokman et al., 1985; *see* Interorganizational Relationships and Networks), and theoretical interpretations of the market as a structure of roles in which the strategy of each producer is based on the observed actions of all others (White, 1981). In spite of a long-standing tradition of interlocking directorates studies, there still exist a number of competing theories about the way these interlocks work (*see* Interorganizational Relationships and Networks).

Relational Aspects of Power

The relational concept of power – derived from Max Weber's classical work – is particularly suitable for NA applications in the study of political phenomena. It has been found that in negatively connected exchange networks power is not a function of centrality, and exchange choices may generate structural transformations of the overall network because of changes in power dependency relations (Cook et al., 1983). In historical analysis, it has been convincingly proposed (Padget and Ansell, 1993) that the rise of the Medici in Renaissance Florence and their increasing political power came about because of network disjunctures within the elite, which the Medici alone spanned. In this study, network structures are identified by block model analysis of different types of interpersonal relations based on marriages, friendship, common economic interests, exchanges, and political alliances.

Measuring Social Capital

The idea of measuring social capital through NA is more recent and has generated renewed interest in these techniques. Extensive empirical research on social capital began in political science in the early 1990s, thanks to Putnam's analysis of civic traditions in modern Italy (1993), and subsequently developed in other fields through the analysis of its economic consequences (Durlauf and Fafchamps, 2005). This preliminary approach extensively used a variety of indicators as proxies for social capital and as variables measuring degrees of civic integration, sociability, participation in voluntary associations, and even opinions about generalized or interpersonal trust taken from subsequent waves of the World Values Survey. In spite of interesting results, this traditional approach has been criticized because it is not based on a straightforward application of the concept of social capital as such. Scholars agree on a relational definition of social capital as "a set of interpersonal relations that are used by actors to fulfill their goals" (Coleman, 1988). Consequently, authors like Lin (2001), Flap (1999), Flap and Völker (2004) have directly applied NA techniques to study the performance of interpersonal relations structures in the realization of one's goals. Chiesi has shown (2007) that structural features of personal networks and their changes over time predict the business success of entrepreneurs. Dufhues et al. (2011) have found a positive effect of social capital on loan repayment behavior. This approach to social capital has also proved fruitful in the inclusion of previous research on strong and weak ties in a single theoretical perspective, as well as other research fields such as social support, ethnic communities, and migration studies. As strong ties tend to be reciprocal and clustered, the term 'bonding social capital' has been proposed in relation to common identity, feelings of belonging, and sometimes promotion of equality, while weak ties, which are typical of 'bridging social capital,' are mainly instrumental for the fulfillment of one's goals.

Large Networks and Their Common Structural Features

A recent interdisciplinary approach, inspired by Barabasi and enhanced by a group of mathematicians, physicists, computer scientists, sociologists, and biologists, has developed a new field aiming at developing a general theory of networks, which is proposed as a Science of Networks in its own. Barabasi and his colleagues (Newman et al., 2006) have pointed out that the study of networks in the field of social sciences has been mainly descriptive rather than analytical, because it has avoided large-scale modeling, due to the difficulty in getting high-quality large-scale network data. Some limits of field research (i.e., validity and reliability of name generator techniques) can be overcome by the recent availability of large-scale computerized sources of relational information coming from online communities, the World Wide Web, mobile phone calls, or transport movements. In this perspective, the analysis of large network data of many kinds in different disciplines has given some evidence of common features and dynamics, such as the power law degree distribution, which is a feature of free-scale networks.

Analytical Concepts and Techniques

Social network measures are based on the representation of a set of points (actors) and a set of lines (ties between actors), so that many concepts and theorems of graph theory can be meaningfully applied. Simple graphs can be depicted in a binary symmetric adjacency matrix. Direct graphs take into account the direction of the arcs and use binary asymmetric adjacency matrices. Signed graphs are used to depict like/dislike relations and use matrices with positive or negative signs in cells. To study weighted relations data sets loose the algebraic properties of binary matrices but gain substantial information on the intensity of ties. Staked matrices are used to represent multiplex ties with multigraphs, while the representation of hypergraphs through asymmetric affiliation matrices allows the study of membership relations.

For each of these, ties different networks can be studied, with the families of descriptive statistics illustrated in **Figure 1**.

Available statistics can be related to the relative position of the actor in the network and to the structure of the network itself. As far as the actor's position is concerned, two subcategories have been developed. The first is devoted to a rich choice among centrality indexes according to the range of the centrality, the kind of network, and the type of graph (Wasserman and Faust, 1994). The underlying theoretical hypothesis is that central actors may have greater opportunities to fulfill their goals than peripheral ones. Measures based on the degree indicate the direct contacts of a point. This is a local centrality measure because the overall structure of the network is not taken into account. In directed graphs, centrality in terms of outdegree can be interpreted as a measure of influence, while in terms of indegree, it indicates prestige or popularity. The concept of neighborhood and its application to centrality measures allows the researcher to choose a given range of distance from the actor, according to the substantive meaning that can be given to the structure of relations. Distance-based measures take account of the relative position of the actor in regard to all other points in the network. For information networks, specific centrality measures based on betweenness have been devised to take into account how a point is important for the transmission of information between any other couple of points.

The second category of actor's position has been developed around the above-mentioned concept of structural equivalence, which is focused on the detection of similar positions of points in the network (Breiger et al., 1975; Doreian et al. in Carrington et al., 2005). The underlying hypothesis is that actors with similar positions have the same constraints and opportunities structure, because they are subject to the same role expectations.

Network structure measures can be subdivided into four categories: size, density, centralization measures, and subset detection. While the network's size is equal to the number of nodes, density is the likelihood that a random pair of points in a network will be joined with a line. Research has shown that dense networks are more effective in controlling and sanctioning than in spreading information. In general, they generate strong ties, redundant information, and constraints, and are therefore not suitable for innovation development and diffusion (Burt, 1992). Network centralization statistics deal with the distribution of ties in the overall network and are based on the analysis of variance of point centrality measures. The more the structure of a connected network is hierarchical, the higher the variance in the distribution of any kind of point centrality measure. Unlike density, whose values are not directly comparable for networks of different size, centralization measures have been standardized through the study of expected variance for different null models, given the number of points and lines (Snijders, 1981).

Subset detection is an area that numerous ad hoc criteria have been developed, according to the substantial meaning attributed to networks. The standard concepts are component (the maximal connected simple subgraph), strong and weak components (in directed graphs, respectively, maximal strongly or weakly connected subgraphs), *n*-clique (the maximal complete subgraph at distance *n*), and blocks (the subset of points with similar structural equivalence). If a multiplicity of ties is involved, the nested graphs technique (Stokman et al., 1985) can detect denser clusters in a network.

Network partition techniques have to do with the definition and analysis of affiliation networks and bipartite graphs. The former is presented in a two-mode matrix, whose rows refer to actors or participants or members and columns refer to events or associations. Groups of actors are defined by their common

Figure 1 A scheme of different types of descriptive network statistics.

participation or membership to the same events or associations, while events and associations can be clustered according to the proportion of their overlapping participants. Traditionally, this approach is typical of interlocking directorates studies and, more recently, of social movements (Diani and McAdam, 2003). The latter is a graph whose nodes can be divided into two disjoint sets such that every tie connects a node in set 1 with a node in set 2. It is another way to represent two modes networks when substantive considerations suggest treating relations in a symmetrical way, without giving priority to one of the two sets.

Relative Merits, Limits, and Perspectives

NA techniques make it possible to specify empirical indicators of relational concepts, to control field hypotheses through the definition and measurement of traditional catch-all concepts like social structure and cohesion and other more recent ones like social capital. The development of network analytical tools has helped to highlight the structures underlying the apparently inextricable complexity of relations among actors in everyday life. From this point of view, the NA approach has the same analytical purpose as other techniques: for instance, those developed in social mobility studies, whose main goal is to simplify descriptions and to standardize measures to use in comparison. Nevertheless, NA offers a wider range of potential applications than traditional surveys, given that it is hard to conceive a social phenomenon that cannot be analyzed as a set of relations among individual or corporate actors. Moreover, research problems can be addressed at both micro- and macrolevels, without changing the research design and techniques, because corporate actors can simply be interpreted as networks of networks.

Major drawbacks counterbalance these advantages, however. It has often been pointed out that NA's abundance of analytical and technical apparatus contrasts with a somewhat limited scope of theoretical and substantive results, which are mostly descriptive or indeed artifacts generated by simplified simulations. While these critics are perhaps applicable to surveys as well, the relative scarcity of empirical results in NA is largely determined by the specific difficulties of field research. Unlike traditional surveys based on standardized questionnaires on the opinions of anonymous respondents, the collection of relational information involves sampling problems (Frank in Carrington et al., 2005) as well as difficulties relating to the reliability of intrusive questions on personal contacts. This is why network analysts often prefer to collect data from documents and repertoires rather than ask direct questions.

Notwithstanding these difficulties, specific network data collection techniques have been extensively used to test specific hypotheses. Ego-centered networks enable the insertion of network information into traditional surveys, provided that for each interviewee his or her personal network at distance 1 is obtained through a combination of the name generator question and the 'who knows whom' question. This procedure yields important insights into the structure of actor's interpersonal relations, but it cannot give an idea of the entire network and it is difficult to assess the validity of name generator instruments, because criterion data from other sources are unavailable. Moreover, the accuracy of data collection depends more on interviewer effects than in normal survey interviews (Marsden, 2005).

To test the more general societal network structure, so-called 'small world experiments' have been devised to probe the connectedness of large networks and structural holes across age, gender, social class, or ethnic groups. Originally, the research problem was put in this way by Travers and Milgram (1969): given any two people in the United States, chosen randomly, persons A and Z, how many intermediate acquaintance links are needed before A and Z are connected? To trace the chains of acquaintances, folders were used, which produced distributions of acquaintance chains. Despite the success of this approach and its recent adaptations to the specificities and potentials of the Web, the methodological debate is still open about the great proportion of uncompleted chains originated by dropouts.

Available archival data can often overcome the problem of representativeness and completeness, but they often suffer from problems related to their actual relevance and to their interpretation. The already-mentioned literature on interlocking directorates is an instance, together with that on scientific citations. Data on interlocks are highly reliable and complete, but their meaning is still a matter of debate in spite of a long-standing tradition that goes back to the beginning of the last century (Stokman et al., 1985). Data on scientific citations are equally reliable and complete but the actual significance of citations and their emerging network has been a matter of debate since the seminal work by de Solla Price in 1965 until the most recent contributions by Moed (2005) in the field of research evaluation.

Large, complete, and reliable data sets on interpersonal communications and exchanges can be obtained from the World Wide Web. For instance, e-mail interactions can be traced and have been more recently studied in their evolution (Kossinets and Watts, 2006), taking advantage of the availability of software programs for the analysis of very large networks. It has been found that the evolution of these networks is less dependent on spatial and social proximity of actors than physical encounters, but mechanisms of homophily and triadic closure (the tendency of choosing new acquaintances who are friends of friends) are equally present. However, the easy accessibility of these databases – which should always follow privacy protection rules – cannot be interpreted as a shortcut to a more general knowledge of human interaction networks. E-mail exchanges – as well as other interaction media like Short Messaging Service, Facebook, or Twitter – are only one part of the different media people use in personal interactions and further research is needed to assess how these are complementary or alternative to face-to-face encounters.

Since the 1980s, the availability of a complete set of structural indicators has encouraged network comparison in order to explain differences in space and changes over time. Two tendencies are emerging. One concerns the development of statistical models that enable comparison between actual networks and models generated by probabilistic assumptions, in order to test goodness of fit hypotheses (Snijders, 2005). The other implies a systematic combination of relational information with attributes of nodes and ties and has yielded promising

results showing that NA and traditional surveys are not necessarily alternative research techniques, as some 'orthodox' network analysts maintain. The advantage of this integrated approach consists in moving from analytical description to causal explanations, where network statistics can play the role of both independent and dependent variables.

As a matter of fact, in the 1970s and 1980s, structural deterministic approaches have stressed the importance of networks in conditioning actors' behavior, attitudes, and well-being, so that static analysis was required because the network was treated as the independent variable. In the past two decades, the most popular assumption has been that actors actively contribute to the formation of their network by building, strengthening, maintaining, and breaking up relationships. From this perspective, the cross-fertilization of NA with social exchange theory seems potentially fruitful, as well as with game theory.

Abstract

While social scientists had been drawing on the abstract idea of social networks clearly since the nineteenth century, which becomes most evident in Georg Simmel's formal sociology, a social network analysis (SNA) grounded in computational models and graphic imagery emerged within the field of small group research in the 1930s. It was Jacob Moreno who introduced the idea of depicting social structure as a network diagram ('sociometry'). Kurt Lewin was an early contributor to the promotion of mathematical models of group relations, and Fritz Heider focused on triads to theorize on what throws groups out of balance. Mostly independent of these ideas, the anthropologist Lloyd Warner adopted a network approach in the study of informal relations between workers and of communities. SNA was further applied by the Manchester school of anthropologists to enhance ethnographic description. Advancing mathematical-formal aspects of SNA at Harvard in the 1970s, Harrison C. White and his collaborators contributed to the establishment of the discipline as a recognized paradigm. In the late 1990s, physicists began to publish work on social networks. Today, SNA has become a multidisciplinary research specialty with distinct theoretical concepts and data-analytic techniques.

The Origins of Social Network Ideas

Social structure has been one of the early key concepts in the social sciences. Social Network Analysis (SNA) is a recently developed set of formal methods for the study of social structures that draws on graph theory in which individuals and other social actors, such as groups and organizations, are represented by points and their social relations are represented by lines. The main theoretical underpinning of SNA is, as Wellman (1988) pointed out, that the structure of relations among actors and the location of individual actors in the network have important attitudinal, behavioral, and perceptual consequences both for individuals and the social structure as a whole. Visual imagery has played a significant role in SNA since its inception. Mathematical and computational models are at the base of more current applications.

Only in the first part of the twentieth century did a handful of social scientists begin to systematically theorize social relationships. Society as a whole was conceptualized as the very tissue of relations. Ferdinand Tönnies (1855–1936) categorized social ties as being either personal and direct ('community') or formal and instrumental ('society'). Herbert Spencer (1820–1903) made a similar distinction between premodern and modern societies by referring to 'ordinary' and 'secondary relations.' Emile Durkheim (1858–1917) theorized the specific structuring of groups as being responsible for the quality of emergent laws and morality, and Gustav Le Bon (1841–1931) was the first to examine the phenomenon of crowd behavior. It was, however, Georg Simmel (1858–1918), a German sociologist whose work stood out against macrolevel theories of scholars such as Max Weber (1864–1920) and Karl Marx (1818–83), who pioneered most explicitly the analysis of dyads (relationships between two persons) and triads (groups composed of three people) as building blocks of social life. Although he never used the term 'social network' as such, his ideas about microlevel structures prove to be a source of inspiration even for current day SNA. Simmel held the view that sociology was no more and no less than the study of interweaving actions in social encounters (Simmel, 1908/2009). He suggested that a consideration of social dynamics caused by the simple addition of a third person could provide insights on society at large, that is, how large structures constrain individuals. While isolated dyads are characterized by individuality and intimacy, triads have a superindividual property: (informal) social pressures are activated, and the variance of behavior as well as interpersonal idiosyncrasies are reduced. Third-party effects may also involve two actors forming a coalition against a third, one actor disturbing the alliance between two others, or one actor even taking advantage of a conflict between two others ('rejoicing third'). It was Simmel's student Leopold von Wiese (1876–1969) who adopted a contemporary terminology of points, lines, and connections to describe social relations (von Wiese, 1924/1932).

The origins of structural research are, however, also located outside the disciplinary boundaries of sociology. Especially the work of scholars in educational and developmental psychology, who were interested in the ways small-group structures affected individual perceptions and actions had a structuralist flavor very early. Helen Bott, for example, set out to document every form of social interaction that occurred among preschool children (Bott, 1928). In fact, she was one of the first to collect ego-centered kinship network data and calculate even network density measures. It is, however, commonly agreed that Jacob Moreno, a student of psychiatry from Vienna who immigrated to the United States in 1925 and championed the field of 'sociometry,' was the main driving force, together with his collaborator, Helen Jennings, in establishing SNA.

Moreno was deeply influenced by Gestalt psychology (Gestalt translates as 'form') developed by mostly German psychologists such as Kurt Koffka (1886–1941), Max Wertheimer (1880–1943), and Wolfgang Köhler (1887–1967) as a protest against behaviorist theories of their day. This school of thought maintained that innate and self-organizing operations of the brain influence the way we see. With respect to the visual recognition of figures, we tend to perceive, for example, whole forms instead of just a collection of lines and curves. Moreno transferred the idea that 'the whole is greater than the sum of its

parts' to the interplay between the social embeddedness of an individual and this person's well-being. He believed that many psychological problems stemmed from failed interactions and that the position of individuals within groups is highly significant for their mental health; Moreno and Jennings (1938) thus spoke of 'psychosocial networks.' Moreno's concern with social structure is mirrored in therapy forms called 'sociodrama' and 'psychodrama,' which aimed at exploring conflicts inherent in social roles. 'Sociometry' was developed as a powerful tool for assessing group dynamics and eliciting graphically subjective feelings between persons. **Figure 1** illustrates typical 'sociograms' featured in the book *Who Shall Survive?* (Moreno, 1934), in which Moreno (and Jennings) probed the causes of runaways at the Hudson School for Girls in upstate New York. The crux of their argument was that the location in the social networks primarily determined whether and when someone ran away.

At first, Moreno's idea to make social structure tangible garnered a great deal of interest, although this turned out to be short-lived. By the 1940s, American social scientists had returned to their focus on the characteristics of individuals (Freeman, 2004).

In the 1940s and 1950s, research on social networks advanced on more than one front, mostly independently of each other. In fact, SNA can be seen as emerging from certain disciplinary trajectories (Prell, 2012), even if scholars working in the field of SNA always crossed disciplines. In the following, the developmental pathways of SNA are outlined in the key disciplines of psychology, sociology, and social anthropology.

Disciplinary Trajectories

(Social) Psychology Trajectory

Kurt Lewin, a German-Jewish émigré and a contemporary of Freud, who after arriving in the United States first held an academic position in Iowa, provided an important intellectual foundation for the development of SNA. His most cited work is *Field Theory in Social Science* (Lewin, 1951), in which he puts forward the idea that behavior is embedded in a psychophysical field consisting of 'valances,' which are analogous in their dynamics to gravitational forces: they pull one toward or push one away. Lewin's field theory was supposed to provide a method of analyzing causal relations among mutual interdependent facts in a concrete situation as perceived by the individual. Lewin tried to formalize his topological concepts: vectors describe the resolution of forces, the lengths represent their strengths, and arrows indicate the direction of field forces. The 'life space,' which contains a person and this person's environment, was divided into regions (family, work, etc.), paths, and barriers. In 1945, Lewin left Iowa to form the Research Center for Group Dynamics at Massachusetts Institute of Technology (MIT). After his sudden death in 1947, most of his coresearchers moved to the University of Michigan ('the Michigan group') and continued to make important contributions to SNA.

Dorwin Cartwright and Frank Harary (1956) extended Fritz Heider's social balance theory (Heider, 1946) which discusses the relations among individuals based on sentiments. In the case of triads, Heider postulated that a balanced state between the three (focal individual P, another agent O, object X) can only exist, if the algebraic multiplication of signs in the triad relation has a positive value. With three sets of possible relationships, each taking one of two values (+, −), eight possible states exist. A triad is harmonious, for example, if there are two negative and one positive relation (e.g., −, +, −): "I don't like person B. B has a dog. I don't like the dog either." One of Heider's propositions is that individuals tend to choose states of balance in their interpersonal relations, which is why the adages 'your friends are my friends' or 'the enemy of my enemy is my friend' adequately summarize core implications of social balance theory. Building on Lewin's work, Cartwright and Harrary translated Heider's diagrams into graph theory and covered more than triadic relationships by asking the following question: What pattern would the interpersonal relations of a group of individuals have if they were balanced? Important among their findings is the 'structure theorem' that "an s-graph [signed graph] is balanced if and only if its points can be separated into two mutually exclusive subsets such that each positive line joins two points of the same subset and each negative line joins points from different subsets" (Cartwright and Harary, 1956: p. 286; **Figure 2**). Subsequently, Davis (1967) generalized balance to clusterability, which allows any number of clusters such that positive arcs appear within clusters and negative arcs between clusters. Davis and Leinhardt (1972) further extended balance theory by including status, which was motivated by the fact that people not only cluster into groups but also adhere to social rankings. They show how directed sentiment relations could generate a structure that is incorporated in a system of hierarchically arranged cliques. These classic papers gave the initial spark for the development of many techniques for identifying cohesive subgroups. One of the most innovative approaches to microstructures was the conceptualization of dyads as a stochastic process in which distribution can be statistically modeled (Holland and Leinhardt, 1977).

In the 1950s and 1960s, Alex Bavelas, another student of Lewin, conducted experiments at the MIT together with colleagues such as Harold Leavitt. He was especially concerned with communication in small groups and hypothesized a relationship between structural centrality and information diffusion processes. In Bavelas (1950), the hierarchy steepness within five-person groups working on a joint task was moderated by installing either a 'wheel' structure, in which all messages could only flow between peripheral members by passing a central actor, or decentralized configurations without limited communication channels. A tentative finding was that centralization was beneficial in the case of simple tasks and detrimental for complex ones. Bavelas was the first to develop a centrality measure, which received much attention and provided an impetus for the refinement of mathematical concepts regarding network structure. At MIT Leon Festinger, R. Duncan Luce, and Albert Perry especially strived for a mathematical formalization of SNA. In a seminal article, Luce and Perry (1949) used graph-theoretic terminology to define cliques as maximal complete subgraphs. What is meant by 'complete' is that every individual is tied directly to every other. Parallel to this, Festinger (1949), who was primarily concerned with the development of group standards, applied somewhat different matrix algebra to identify cliques. In either case, the

Attractions and repulsions take the form of isolation.

Isolation. Subject is attracted to six individuals outside of his group (outside individuals are symbolized by a double circle) who do not reciprocate.

Isolation. Subject is attracted to four individuals outside of his group and rejects two more; they do not reciprocate; three others who are attracted to him he does not reciprocate.

Isolation. Subject is attracted to five individuals within his group; they respond with indifference.

Mutual attractions between three individuals take the form of a triangle but each of the subjects is otherwise rejected and isolated within his own group; the result is an isolated and rejected triangle of persons.

Five subjects each isolated and rejected within his own group reject and isolate each other.

Two subjects each otherwise isolated in his own group form a pair of mutual attraction; the result is an isolated pair.

Subject rejects six and is rejected by fifteen individuals within his own group; is rejected further by two individuals outside of his own group. The result is an isolated and rejected individual.

Figure 1 Example of sociograms. Source: Moreno, J.L., 1934. Who Shall Survive? Nervous and Mental Disease Publishing Company, Washington, DC, p. 116.

A signed graph of four points and five lines. Solid lines have a positive sign and dashed lines a negative sign. If the points stand for people and the lines indicate the existence of a liking relationship, this s-graph shows that *A* and *B* have a relationship of liking, *A* and *C* have one of disliking, and *B* and *D* have a relationship of indifference (neither liking or disliking).

implicit assumption motivating clique analysis was that actors who maintain cohesive bonds were prone to act similarly. Subsequently, Cartwright and Harrary proposed alternative ideas for clique detection, such as the maximal strong component idea, which implied loosening the clique concept by allowing for indirect links of various lengths. Thus a maximal strong component is a network subgroup in which each actor can reach other actors directly or indirectly, and no further actor can be added without reducing the mutual reachability. At the time these formalizations of SNA were put forward, the development of large computers had already commenced, although computational methods for findings cliques were still rare.

The approach of Bavelas and his colleagues at MIT spurred innovative approaches to studying the social fabric in the post-World War II era. Ithiel de Sola Pool, a political scientist, and Manfred Kochen, a mathematician at IBM, drew up mathematical models for tackling the vexing 'small-world problem': If two persons are selected at random from a population, how many acquaintances are needed to create a chain between them? While de Sola Pool and Kochen turned to mathematical estimations because of a lack of data, the social psychologist Stanley Milgram came up with an ingenious experiment. Randomly chosen 'starters' in Nebraska were given a letter to deliver to 'target persons' in Massachusetts by sending it on to acquaintances whom they thought to be closer to the target. The idea was to test empirically how many intermediaries were needed to reach someone. Milgram's initial results (Milgram, 1967) led to the now popular notion of 'six degrees of separation,' which touched off a storm of further work across numerous disciplines. Replications, however, provided rather mixed findings on the validity of the experimental setting.

Sociology Trajectory

Although only collaborating for 6 years in the Anthropology Department and the Business School at Harvard, the anthropologist W. Lloyd Warner and the psychologist Elton Mayo produced work that was to become a historical landmark. Industrial psychologists relied on Warner and Mayo when faced with inconsistent effects of the physical work environment on worker productivity. The two men had discovered that improving lighting conditions boosted worker morale, but restoring lighting to its original state did not lead to deterioration in productivity. The Harvard team turned its initial psychological focus to the social structure that was systematically observed in a small group of workers putting together telephone switching equipment in the 'bank wiring room' of Western Electric Corporation in Cicero, Illinois ('Hawthorne Works'). This field study, described in great detail by Roethlisberger and Dickson (1939/2003), was the first to use sociograms to describe formal and informal relations between workers and is today among the classic readings in sociology (see **Figure 3**).

Observations revealed that workers were more responsive to social forces within their (informal) peer groups than to physical incentives. There was, however, no attempt to use graphs to identify sociometrically defined 'cliques.' John Scott (2013: p. 22) even concludes that the authors "appear to lack any theoretical understanding of how social networks might shape the behaviour of individuals" (Scott, 2013: p. 22).

Later on, Lloyd Warner (Warner and Lunt, 1941) helped disenchant the American myth of a classless society by detecting social divisions and rank orders of social participation in Newburyport, Massachusetts ('Yankee City'). Recognizing that the research site was ill-suited to shed light on racial demarcation in social stratification, Warner and his team embarked in further studies on an anthropological investigation of the 'Deep South' (Davis et al., 1941). Unlike in the Hawthorne study, the authors used matrices extensively to study the structural embedding of actors. Generating a data set that captured the

participation of 18 women in 14 events enabled them, for example, to identify cliques and social status among small groups. One of their findings was that social cliques (in colored societies) are composed of different layers: a 'core' of actors in the center of nearly all clique gatherings, a 'primary circle' of those who jointly participate with core members but do not stick together within one subgroup, and a 'secondary circle' of less-intimate friends who rarely participate.

This field research in the precomputer age emerged in parallel with advances in sociometry concerned especially with relational patterns in small groups. Harvard professor George Homans was the first to systematically review and synthesize the bulk of experimental and observational studies dealing with the subject. His path-breaking book *The Human Group* (Homans, 1950) is packed with much-cited conceptual schemes, such as the distinction between what he called an 'external system' (structure that prescribes human interaction, e.g., kinship) and an 'internal system' (processes within groups). Internal structural buildup is generated through interactions based on feeling or participations in common activities, whether or not this is dictated by the external system. Activities and common sentiments would generally lead to clique formation and instill social solidarity from within. Homans also reanalyzed data from the 'Hawthorne' and 'Deep South' studies. By rearranging the rows and columns of *women x events* matrix used by Davis et al. (1941), he aimed at detecting the existence of cliques – a method that is analogous to what has subsequently come to be called blockmodeling. However, he was far from advancing mathematical thinking in SNA.

A further strand of structural thinking within sociology developed in the 1950s at Columbia University, where the lifelong collaborators Paul Lazarsfeld and Robert K. Merton supervised many students, such as Peter Blau, James Coleman, and Charles Kadushin, who advanced the standards of modern SNA. Blau, an exponent of social exchange theory, refined the notion of homophily in SNA and established empirically that multigroup memberships 'crosscutting social circles' promote intergroup relations. Coleman established social capital, the resources inherent in the relations between and among actors, as a key concept in SNA. In a pioneering study on diffusion in social networks, he showed, together with Elihu Katz and Herbert Menzel, how doctors' willingness to prescribe new antibiotics spread through professional contacts. Building on Simmel's notion of social circle, Kadushin explained people's interest in consulting a psychotherapist not by individual influences but rather by memberships in intersecting social groups ('knowing others in therapy, knowing others with similar problems, asking friends for a referral'). Lazarsfeld himself applied newly improved survey technologies to investigate the influence of mass media. One of his main findings was that voters were not directly influenced by media during election time but rather by so-called opinion leaders in medium-sized communities who pass on media information through interpersonal communication (two-step flow of communication, Lazarsfeld et al., 1944).

Social Anthropology Trajectory

A further key contribution to the development of SNA was the foundation of the Department of Social Anthropology and Sociology in the 1950s at the University of Manchester, headed by Max Gluckman. In Manchester, a dynamic group of researchers, including Elisabeth Bott (also affiliated with the London School of Economics), John Barnes, J. Clyde Mitchell, and Siegfried Nadel, popularized the application of social network methods in ethnography. The Manchester school was deeply influenced by Alfred R. Radcliffe-Brown's structural perspective, which they sought to take in a novel direction. Radcliffe-Brown (1940) argued that anthropologists should investigate social phenomena by using methods similar to those in physics, which essentially meant relying on mathematics and analyzing structures such as kinship in terms of their function for maintaining societies across the globe. While Gluckman and his collaborators dismissed functional ideas of social equilibrium and acknowledged conflict as an inherent part of societies, they nevertheless refined the idea that social relations are embedded in wider networks.

In the decade after World War II, these anthropologists mostly carried out fieldwork in what was then British Central Africa (now Zambia, Zimbabwe, and Malawi), which gave theoretical force to such concepts as intercalary roles or crosscutting ties. Gluckman, for example, developed the intercalary theme when analyzing the authority roles of village headmen in rural societies, who were subject to conflicting pressures from fellow villagers and political superiors. At the conceptual level, societies were no longer seen as being monolithic, but rather as a pattern of relationships "obtaining between actors in their capacity of playing roles relative to one another" (Nadel, 1957: p. 12). The initial stimuli to direct study toward social networks were provided especially by Barnes' paper and Bott's book (Barnes, 1954; Bott, 1957). When studying a Norwegian fishing village, Barnes neglected the traditional anthropological concepts of geography, politics, and economics and focused instead on primordial relations such as kinship, friendship, and neighborhood ties, which combine to constitute what he called a 'network.' He is often regarded as the first person to have conceptualized the term, which he imagined as consisting 'of a set of points some of which are joined by lines' (Barnes, 1954: p. 237). Bott (1957) applied this concept to the study of the conjugal roles in families from London. She argued that the degree of segregation in the role-relationship is a function of the configuration of the network of friends and relatives associated of each spouse. For example, if husbands and wives are embedded in joint networks, the members of these external social networks can develop norm consensus and influence how equally spouses interact and share domestic household tasks. She was one of the first to theorize that dense and multiplex networks of ties have a strong norm-enforcement effect on network members, and she made use of sociograms to illustrate differences between dispersed and connected family networks (**Figure 4**).

Mitchell, who continued the Manchester tradition of working in British colonial Africa, made important contributions to the formalization of SNA. In a widely cited introduction (Mitchell, 1969), he suggested a series of conventions, still valid today, on how to model social networks using graph theory and distinguished between total and partial networks. The total network of society is composed of "the general ever-ramifying, ever-reticulating set of linkages that stretches within and beyond the confines of any community or

Figure 4 Schematic comparison of the networks of two families. Source: Bott, E., 1955. Urban families: conjugal roles and social networks. Human Relations 8, 348.

organization" (Mitchell, 1969: p. 12). In actual research, it is therefore imperative to select particular aspects of total networks, which means either focusing on ego-centered networks around particular individuals or on a particular aspect of social activity, such as friendship.

Scott (2013) argues that the reason the breakthrough leading to the study everywhere of social networks in all fields of social life was not made in Britain was the great emphasis on the informal side of communications in mostly ego-centered networks. However, the knowledge of the British anthropologists diffused quickly across the Atlantic and was quite commonly incorporated into a more sociological analysis of social structure, because British empiricism fit well with the American penchant for quantitative measurement and statistical analysis (Wellman, 1988: p. 23).

The Harvard Breakthrough

In the 1970s, the center of gravity in network research shifted to sociology. By the time that Mitchell (1969) published his timely review article, a group of American researchers led by Harrison White had begun to revolutionize the formal methodology of SNA. Reflecting his mixed background in mathematics, physics, and sociology, White's teaching and research at Harvard revolved around algebraic models of social structure. A key advance was the CONCOR algorithm, developed by White and his students, to identify a social network's structurally equivalent actors. An equivalence strategy (Lorrain and White, 1971) clusters individuals on the basis of relational similarity, that is, individuals are said to be 'structurally equivalent,' if they are characterized by identical patterns of relationship with other network members (but do not necessarily have mutual awareness of one another). Edward O. Laumann, White's first Harvard PhD student, was curious about the way people form, maintain, and dissolve relationships with others and about the impact of such networks on identities and behavior. Consequently, he pioneered multidimensional scaling (MDS) in community studies. Laumann and Louis Guttman (1966) asked 422 male residents of Cambridge and Belmont, Massachusetts, about the occupations of their seven alters (interalia the three closest friends). Then, an early form of MDS was applied to a table featuring the respondents' occupations in rows and the alters' occupations in columns. The most fitting solution appeared to be three-dimensional, the first dimension being interpreted as indicating occupational prestige. Two other students, Nancy H. Lee and Mark Granovetter, chose a less algebraic social network approach to the studies of illegal and labor markets. Lee figured out the condition under which women searching for an (illegal) abortion successfully activate social networks to gain indirect contacts with others who might help. Granovetter made the point that the economist's idea of a 'perfect labor market' misses the fact that labor-market information is often transmitted as a byproduct of other social processes. What matters are contacts. His idea that weak ties (corresponding to acquaintances) are superior to strong ties (corresponding to friends) for providing support in getting a job, inspired a vast research program on the role of social networks in the labor market (Granovetter, 1973). It also sparked the interest of sociologists to study the social embeddedness of economic phenomena in general, as, for example, the consequences of network positions of firms for their performance. The Harvard setting proved to be stimulating to many other researchers, among them Peter Bearman, Phillip Bonacich, Kathleen M. Carley, Joel Levine, and Barry

Wellman, who remained at the forefront of the field. It was this diverse group of US-American researchers that established SNA as a formal method in social science research and influenced work across the globe.

Over a long period, SNA ideas have more or less evolved in the different fields referred to above. The late 1970s, however, witnessed the emergence of a unified research field. Mathematics, the dominant force in the field, helped advance commonly understood and shared terms. Computer programs, above all UCINET developed by Lon Freeman, Martin Everett, and Steve Borgatti, standardized the analysis of social network data. Annual conferences facilitated the communication between different schools, and the foundation of the International Network of Social Network Analysis (INSNA) and its newsletter *Connections* completed the integration of the field. Today different academic journals, such as *Social Networks*, provide an institutionalized forum for representatives of different disciplines, ranging from anthropology to communication science.

The Application of SNA across Disciplines

Having become a standard methodology, SNA experienced changes, the most striking development being the growth of interest apparent among physicists in applying network ideas to social phenomena. First, Watts and Strogatz (1998) published on small worlds. Within the social sciences, small worlds were first studied in depth by Milgram, whose experiments on forwarding letters (see above) established theories on 'six degrees of separation.' Watts formalized the features of small-world networks, in which most nodes are not neighbors but can be reached from every other node by a small number of steps, as the coincidence of high local clustering and short global separation. Watts and Strogatz (1998) show small worlds to be widespread not only in biological and man-made networks, but also in social ones. Barabási (2002) studied the distribution of network connections that grew because new nodes were added; to do this, he used different examples such as sites in the World Wide Web or links between screen actors. He discovered networks not to be random but to contain hubs – nodes with a very high number of links. In such networks, the distribution of linkages follows a power law in that most nodes have but a few connections while others have a huge number of links. In that sense, the network has no 'scale.' Scale-free networks prove to be widespread in the social world and seem to be robust against accidental failures.

Especially the work of Watts and Strogatz steered much interest in network analysis within the physics community. Within few years physicists produced more articles on small worlds than the social network community had turned out in almost a half century. However, Freeman's analysis of citations clearly shows that physicists rarely cite work of social network analysts, and social scientists are reluctant to engage with the models of physicists (**Figure 5**).

Many other disciplines have a heightened interest in SNA. Political scientists use the small-world concept to study information cascades, map out terrorist networks, study advocacy networks, or the influence of social relationships on legislative behavior. Epidemiology is turning toward SNA to test contagion theories on phenomena as diverse as obesity, smoking, or happiness. Communication science uses (semantic) network analysis to examine differences between blog posts and professional journalism or the structure of international news flows. Computer science researchers study changes in trust, migration, and mobility in online network-like communities. Witnessing decades of explosive growth, SNA academic journals such as *Network Science* and research centers emerged that aim at bridging and bonding disciplinary bonds. More than ever SNA has become a multidisciplinary endeavor.

Conclusion

The roots of SNA are diverse. Network theorizing in the social sciences dates back to the work of Georg Simmel, from the last decade of the twentieth century (Simmel, 1908/2009).

Moreno's network visualizations that displayed up to 435 individuals (Moreno, 1934) marked the beginning of sociometry, the precursor of SNA. The approach to represent social relations by graphs of points and lines was especially taken up by three disciplines: Social psychology, sociology, and social anthropology. Heider's balance theory that aimed at describing 'equilibrium' properties of interpersonal relations inspired the work of Cartwright and Harary, who studied more complex cases of structural balancing (i.e., groups with more than three elements). Alex Bavelas examined the impact of different communication network structures on the ability of groups to solve problems. In general, early social psychological work mostly focused on (positive and negative) interpersonal relations within smaller groups and their implication for behavior in social contexts. The network approach to social structures such as status systems in typical American communities (Warner and Lunt, 1941) provided insights that were more amenable to sociology. Social anthropology was primarily concerned with kinship networks. While most of the pioneering studies in SNA transcended disciplinary boundaries only to a limited extent, the pocketing of social network concepts and theories within single disciplines is today seen less. Especially, the newly established field of 'network science' avoids compartmentalization, yet consolidating a common language and methodological toolbox (Vedres and Scotti, 2012).

While SNA is experiencing rapid growth in participants, controversy surrounds the issue whether SNA is 'just' a methodology or also a theory with a set of clearly defined propositions. Borgatti and Halgin (2011) identify two models that underlie network theorizing: the network flow model and the bond model. The first being identified, for example, with the strength of weak ties theory (Granovetter, 1973) that predicts how information flows through a given network and generates outcomes for the nodes. The second being best represented by theories on power in exchange network, which underlying theme is how network ties align and coordinate action in order to enable many nodes to act as a single node with greater capabilities. What is rather uncontroversial is that SNA comes with a set of powerful heuristics that help to analyze as diverse phenomena as corruption or the spread of diseases.

Abstract

Measures of network centrality assess the importance of elements in arrays of relationships linking entities, such as persons, organizations, or documents. Important entities may have many contacts, be related to other important entities, be near other entities, or be positioned between others. Most centrality measures refer to entities, but some refer to relationships. Network-level centralization statistics measure variation in centrality across entities within a network. This article presents centrality measures for common forms of network data, including undirected binary networks, valued networks, directed networks, and two-mode networks of relationships that connect distinct types of entities.

Overview

Network analysis examines relationships among entities, such as persons, organizations, or documents. Operating at multiple levels, it describes and makes inferences about relational properties of individual entities, of subsets of entities, and of entire networks. Measures of network centrality are widely applied indices for describing positions of individual entities within networks.

Centrality is a covering term, referring generally to an element's 'importance' within a network. Visual depictions of networks usually place important elements in central locations. Different centrality measures correspond to distinct ways in which entities or relationships are involved in connectivity patterns: having many contacts, being near other entities, or being positioned between others. Social science applications use centrality measures to represent diverse theoretical concepts including power, influence, status, and prestige, among others.

This article begins by introducing network concepts that are helpful in understanding centrality measures. It then presents major centrality measures for the 'undirected, binary-valued' network data that many measures assume. Following that are variations on those measures suitable for other common data types, including valued, directed, and 'two-mode' arrays. For more comprehensive discussions of network centrality measures, see Koschützki et al. (2005) or Newman (2010).

Foundations

An undirected network data array consists of a set of entities and a set of pairwise relationships among them. Each relationship signifies only that two entities are somehow affiliated (e.g., that John and Sue communicate), making no distinction between 'sending' and 'receiving' entities.

Formally, entities are termed *vertices*, and indexed from 1 to N. Relationships in undirected networks are called *edges*. A binary-valued indicator variable x_{ij} indicates whether an edge between vertices i and j exists ($x_{ij} = x_{ji} = 1$) or not ($x_{ij} = x_{ji} = 0$). Most applications treat self-relations x_{ii} as undefined, setting them to 0 by convention, so an N-vertex network may include as many as $N(N-1)/2$ edges. When relationships are valued, weights w_{ij} give their intensity.

Figure 1 depicts an undirected, binary-valued network with 11 vertices labeled A–K. Lines indicate 12 pairwise relationships or edges; for example, a relationship exists between vertices A and B, but not between A and D.

Many centrality measures involve features of *indirect* relationships consisting of two or more concatenated edges. A *walk* – any sequence of edges beginning at one vertex and ending at another – is a very general type of indirect relationship. A walk may pass through a given vertex more than once and/or traverse a given edge repeatedly. In a *path*, no vertex or edge appears more than once. The number of edges in a path is its *length*, and a shortest-length path between two vertices is called a *geodesic*. The number of geodesics linking vertices i and j is symbolized g_{ij}; the length of the geodesic(s) linking them gives their *geodesic distance* d_{ij}. If no path of any length connects two vertices, their geodesic distance is infinite.

Figure 1 An undirected, binary-valued network. Constructed using igraph (Csárdi, Gábor, Nepusz, Tamás, 2006. The igraph software package for complex network research. InterJournal Complex Systems 1695).

In Figure 1, the vertex sequence (A, B, D, F, D, C) gives a walk of length 5 from vertex A to vertex C. It passes through vertex D twice, so it is not a path. The sequence (G, I, J) is a length-2 path from G to J; it is not, however, a geodesic: a length-1 path (i.e., an edge) also links G and J. Two ($g_{AD} = 2$) geodesic paths – (A, B, D) and (A, C, D) – connect vertices A and D, at geodesic distance $d_{AD} = 2$.

Centrality Measures for Binary-Valued Undirected Networks

Freeman (1979) inventoried measures of network centrality for vertices, elucidating their conceptual foundations. These measures were first developed for studying communication and related group processes; most were formulated for undirected, binary-valued network data. Borgatti and Everett (2006) highlight two primary ways in which a vertex can be structurally important, distinguishing between *radial* and *medial* measures. Radial measures focus on the direct and indirect relationships that originate from (or end at) a vertex, and vertices linked to others via short-distance relationships. Medial measures instead call attention to vertices situated in intermediary positions along walks or paths that connect pairs of others.

Radial Measures

Degree Centrality

The simplest centrality measure is a vertex's *degree*, its number of direct relationships to other vertices. For communication networks, Freeman (1979) suggests that degree centrality reflects a vertex's activity level. Degree centrality captures a vertex's importance in its locality only, ignoring its involvement in indirect relationships. The degree centrality of vertex i in an undirected network is

$$C_D(i) = \sum_{j=1}^{N} x_{ij}$$

Degree centrality counts the number of edges incident to a vertex, so $C_D(i)$ values can be greater when a network has more vertices. Normalized centrality measures adjust for network size by expressing a vertex's centrality as a fraction of its maximum possible level, such that the largest possible normalized centrality is 1. A normalized version of degree centrality is

$$C'_D(i) = \frac{C_D(i)}{N-1}$$

since a vertex can be linked to at most $N - 1$ others.

Table 1 reports scores for vertices in Figure 1 on several centrality measures discussed here. Vertex G's degree centrality is largest (4), while several peripheral vertices (E, H, and K) have the lowest degree (1). Vertex G could be linked to as many as 10 others, so its normalized degree centrality is 0.40.

Degree centrality gives the number of other vertices in a vertex's immediate neighborhood or 'first-order zone.' This idea generalizes readily to a measure of the size of a vertex's 'mth-order zone': the number of other vertices it can reach via geodesics of length m or less:

$$C_{Dm}(i) = \sum_{\substack{j=1 \\ (i \neq j)}}^{N} I(d_{ij} \leq m)$$

where $I(.)$ is an indicator variable. For $m = 1$, this yields degree centrality. If m equals the 'diameter' of a network (i.e., the length of the longest geodesic between any pair of vertices), one obtains a *reachability* index, the number of others that a vertex can reach via paths of any finite length. In Figure 1, vertex F can reach 8 of the other 10 vertices using paths of length 1 or 2, so $C_{D_2}(F) = 8$. $C_{D_6}(i) = 10$ for all vertices, since each lies within geodesic distance 6 or less of all the others.

Distance-Based Centrality Measures

Other radial measures take account of a vertex's proximity to all others, not just those that are nearby. Many such measures depend on geodesic distances, on the reasoning that if it is costly to activate relationships or secure the cooperation of intermediaries, transmitting information or concluding resource transactions using shortest paths will be most efficient.

Table 1 Selected centrality scores for vertices in Figure 1

	Centrality measure						
Vertex	Degree $C_D(i)$	Shortest-path closeness $C_C(i)$	Eccentricity $C_E(i)$	Shortest-path betweenness $C_B(i)$	Reflection (eigenvector)[a] $C_R(i)$	β-Centrality (β positive)[a] $C_\beta(i)$, $\beta = 0.31$	β-Centrality (β negative)[a] $C_\beta(i)$, $\beta = -0.31$
A	2	0.029	0.167	1.0	0.143	0.225	0.219
B	2	0.034	0.200	3.5	0.165	0.237	0.220
C	3	0.037	0.200	12.5	0.196	0.304	0.400
D	3	0.045	0.250	25.0	0.272	0.353	0.398
E	1	0.028	0.167	0.0	0.078	0.123	0.081
F	2	0.048	0.333	25.0	0.325	0.320	0.084
G	4	0.045	0.250	27.0	0.547	0.493	0.654
H	1	0.032	0.200	0.0	0.217	0.182	0.002
I	3	0.036	0.200	9.0	0.442	0.388	0.353
J	2	0.034	0.200	0.0	0.393	0.331	0.098
K	1	0.027	0.167	0.0	0.176	0.149	0.096

[a]Scaled such that sum of squared scores is 1.

In this view, central vertices are those linked to others by short distances. Such vertices can reach others more expeditiously, and hence are attractive as loci at which innovations or interventions can be introduced into a network. They require cooperation from fewer go-betweens to disseminate something widely, and hence are more autonomous. Since the geodesic distance d_{ij} gives the minimum number of edges separating two vertices i and j, the sum of all geodesic distances from a given vertex (i) to others $\left(\sum_{\substack{j=1\\(i\neq j)}}^{N} d_{ij}\right)$ gives the total number of edges between it and the rest of the network. The sum is smaller for more central vertices; inverting it (so that more central vertices have higher scores) gives a *shortest-path closeness* centrality measure:

$$C_{\mathrm{C}}(i) = \frac{1}{\sum_{\substack{j=1\\(i\neq j)}}^{N} d_{ij}}$$

When edges link a vertex to all others, the sum $\sum_{\substack{j=1\\(i\neq j)}}^{N} d_{ij}$ takes its minimum value, $N-1$. Hence the reciprocal of the average geodesic distance from a vertex yields a normalized closeness measure:

$$C'_{\mathrm{C}}(i) = \frac{N-1}{\sum_{\substack{j=1\\(i\neq j)}}^{N} d_{ij}}$$

By using the length of geodesics as a distance index, $C_{\mathrm{C}}(i)$ assumes that vertices locate and use geodesic paths when transacting or communicating with one another. This is not always tenable (Borgatti, 2005), especially for unplanned flow processes. Social actors may be aware only of their local ties and unable to identify shortest paths. Moreover, they do not always deliberately seek to route information or resources to a specific location.

One might posit that flows in networks instead follow *random walks* from one vertex to another. A random walk from vertex i to vertex j begins along a randomly selected edge from i to another vertex k; it next traverses a randomly selected edge emanating from k, continuing on until a randomly selected edge reaches vertex j. Though the length of such walks varies by chance, the expected number of edges m_{ij} in a random walk from i to j can be calculated (Koschützki et al., 2005) and regarded as the distance separating them. Parallel to $C_{\mathrm{C}}(i)$, a *random-walk closeness centrality* measure is the inverse of the sum of the expected random-walk distances from vertex i to all others:

$$C_{\mathrm{CRW}}(i) = \frac{1}{\sum_{\substack{j=1\\(i\neq j)}}^{N} m_{ij}}$$

Calculating closeness centrality measures entails complications in 'disconnected' networks where at least one pair of vertices is not linked by any path (or walk), so that their geodesic (or expected random-walk) distance is infinite. Closeness centrality is then 0 because the sums in the denominators of $C_{\mathrm{C}}(i)$ and $C_{\mathrm{CRW}}(i)$ are infinite if a vertex has no indirect connection to even one other. Many therefore suggest calculating closeness centrality only within 'connected components' of a network, i.e., subsets of vertices within finite geodesic distances of each other. Others recommend imputing some finite value (such as N) to infinite distances, but imputing a value for infinity is necessarily arbitrary. Still another approach (Newman, 2010) redefines the closeness centrality of a vertex as the sum of the inverse geodesic distances (rather than the inverse of the sum):

$$C^{*}_{\mathrm{C}}(i) = \sum_{\substack{j=1\\(i\neq j)}}^{N} \frac{1}{d_{ij}}$$

here, length-1 geodesic distances add most to a vertex's closeness centrality, while infinite ones contribute nothing. The random-walk closeness measure $C_{\mathrm{CRW}}(i)$ can be modified analogously.

A distinct distance-based centrality measure introduced by Hage and Harary (1995) depends on a vertex's *eccentricity*: the maximum geodesic distance emanating from it. Vertices with low eccentricity lie within a comparatively short distance of all others, and hence are central:

$$C_{\mathrm{E}}(i) = \frac{1}{\max_{j}(d_{ij})}$$

In networks representing routes linking places, vertices having high $C_{\mathrm{E}}(i)$ scores are attractive locations for facilities designed to respond to unpredictable events that might occur anywhere.

In **Figure 1**, vertex F has the highest shortest-path closeness. The sum of geodesic distances to F is 21, so $C_{\mathrm{C}}(\mathrm{F})$ is 0.048, with normalized closeness 0.478. Vertices D and G, each with closeness 0.045, come next. Vertex F also has the highest eccentricity closeness; it is within geodesic distance 3 of the other 10 vertices, so $C_{\mathrm{E}}(\mathrm{F}) = 0.33$. For the other vertices, eccentricity centrality is 0.25 or less.

Measures Involving Reflection/Feedback

The intuition that an entity acquires importance through affiliations with other important entities is widespread; one's reputation reflects that of one's associates, and vice versa. Bonacich's (1972) centrality measure is one of several that rest on this idea. It posits that a vertex's centrality is proportional to the centrality-weighted sum of its connections to others. That measure, $C_{\mathrm{R}}(i)$, satisfies the equation

$$C_{\mathrm{R}}(i) = \frac{1}{\lambda}\sum_{j=1}^{N} x_{ij} C_{\mathrm{R}}(j)$$

It outwardly resembles degree centrality, but edges linking a vertex to central vertices convey more importance than those connecting it to peripheral ones. The expression is circular: vertex i's centrality depends on that of its contacts, but their centrality in turn rises with i's. The relative magnitudes of the reflection centrality scores implied by this feedback process can be obtained using the largest

'eigenvalue' (λ) derived from the set of $N(N-1)/2$ network variables $\{x_{ij}\}$ in an undirected network. The $C_R(i)$ values are proportional to elements of the associated 'eigenvector'; they may be rescaled as long as this proportionality is maintained. $C_R(i)$ therefore is often termed *eigenvector* centrality.

With $C_R(i)$ scores scaled such that their squared values sum to 1, vertex G in Figure 1 has the highest reflection centrality, 0.55. By virtue of their connections to G, several other vertices also have relatively high reflection centrality: $C_R(F) = 0.33$, $C_R(I) = 0.44$, and $C_R(J) = 0.39$. Vertex D's reflection centrality is lower, at 0.27; although its degree (like I's) is 3, D's relationships link it to less central others.

The reflection or eigenvector measure $C_R(i)$ assumes that connections to central others enhance a vertex's centrality. Under some circumstances – notably in some bargaining situations – being near central others may be a disadvantage. Bonacich's (1987) flexible *β-centrality* measure generalizes $C_R(i)$, allowing the dependence of a centrality score on those of its associates to vary in both direction and intensity. β-centrality is defined as

$$C_\beta(i) = \sum_{j=1}^{N} (\alpha + \beta C_\beta(j)) x_{ij}$$

Parameter β governs the interdependence among β-centrality scores, while α controls their scaling. Analysts must supply values for both parameters; the magnitude of β should be less than $1/\lambda$.

Bonacich (1987) expresses β-centrality as a weighted sum of the number of walks (of any length) from a vertex, giving less weight to longer walks. The measure takes more account of longer walks when β is larger; for β near $1/\lambda$, it approaches reflection centrality. When β is smaller, $C_\beta(i)$ measures a more local centrality: if $\beta = 0$, $C_\beta(i)$ is proportional to degree centrality. A negative β means that direct connections (and odd-length walks) to central vertices reduce a vertex's β-centrality, while length-2 (and even length) indirect connections to central vertices heighten it.

With $\beta > 0$, β-centrality values for vertices in Figure 1 resemble those for reflection centrality. For $\beta = -0.31$, however, vertices G (0.65), C (0.40), and D (0.40) have high β-centrality. Vertex F, directly linked to both D and G, has a much lower value, $C_\beta(F) = 0.10$. Note, in contrast, that being connected to G increased F's reflection centrality.

Medial Measures

Vertices positioned between the endpoints of paths or walks have the potential to create – or limit – connectivity between others, a distinct form of structural importance. By virtue of their location, they can regulate flows within a network, and hence can be go-betweens, gatekeepers, bottlenecks, brokers, and the like. Centrality indices sensitive to this control capacity are known as medial measures.

Freeman (1979) introduced a widely used medial centrality measure based on geodesics. A focal vertex k lies between two other vertices i and j if it is an intermediary on one or more geodesics connecting them; $g_{ij}(k)$ denotes the number of times k is between i and j. Comparing this to g_{ij}, the total number of geodesics between i and j, gives the fraction of the i-j relationship that k is in a position to control:

$$b_{ij}(k) = \frac{g_{ij}(k)}{g_{ij}}, k \neq i, j$$

Summing across all pairs of vertices leads to a measure of vertex k's *shortest-path betweenness centrality*:

$$C_B(k) = \sum_{i=1}^{N} \sum_{j=i+1}^{N} b_{ij}(k)$$

$C_B(k)$ reaches its maximum possible value, $(N^2 - 3N + 2)/2$, when vertex k lies along the only geodesic linking each of the $(N-1)(N-2)/2$ pairs of other vertices. A normalized betweenness centrality measure is therefore:

$$C'_B(k) = \frac{2C_B(k)}{N^2 - 3N + 2}$$

As noted for closeness measures, assuming that geodesics can be located and used can be problematic. Newman (2005) developed an alternative betweenness measure based on the premise that flows in networks follow random walks rather than geodesics. It first determines the expected number of times that a random walk between vertices i and j passes through vertex k. Aggregating that across all vertex pairs gives random-walk betweenness centrality.

In Figure 1, vertex F lies on the only geodesic linking D and G, so $b_{DG}(F) = 1$; B is on one of the two geodesics between A and D, so $b_{AD}(B) = 0.5$. Vertex G has the highest shortest-path betweenness centrality, with $C_B(G) = 27$, i.e., it is in a position to control the equivalent of 27 geodesics connecting other vertices; G's normalized score is 0.60. Vertices D and F have slightly lower normalized betweenness (0.56), while several vertices (E, H, J, K) lie along no geodesic paths and so have 0 betweenness.

Edge Centrality

Centrality measures usually describe the network positions of vertices, but they can be calculated for edges as well. Most widely applied is a medial measure, edge betweenness, that identifies edges that are most crucial to maintaining a network's connectivity.

By analogy to $C_B(k)$, an edge's betweenness is the number of times it lies on geodesics connecting pairs of vertices.

$$C_B(x_{km}) = \sum_{i=1}^{N} \sum_{j=i+1}^{N} b_{ij}(x_{km}) = \sum_{i=1}^{N} \sum_{j=i+1}^{N} \frac{g_{ij}(x_{km})}{g_{ij}}$$

where $g_{ij}(x_{km})$ is the number of times an edge linking vertices k and m lies on a geodesic linking vertices i and j. In Figure 1, both the (D, F) and (F, G) edges are on geodesics between 30 pairs of vertices (55% of all 55 pairs). Removing either edge would partition this network into two disconnected components.

Centralization

Corresponding to each vertex-level centrality measure is a network-level *centralization* statistic. Centralization measures the

extent of inequality among vertex centrality scores. A generic definition of centralization sums the differences between each vertex's centrality score and that of the most central vertex:

$$C_X = \sum_{i=1}^{N}\left(\max_k (C_X(k)) - C_X(i)\right)$$

where X references a particular centrality measure. When all vertices have identical centrality, centralization is 0; it grows larger as differences among scores increase. Dividing by the largest value C_X can take in any network having N vertices yields a normalized centralization score that varies between 0 (for equal centrality values) and 1 (for the largest possible differences from the maximum score). The largest possible C_X usually arises for a 'star' network with $N-1$ edges linking one central vertex to each other; for the reflection/eigenvector measure $C_R(i)$, C_X is maximal in a graph with a single edge.

In Figure 1, degree centrality is largest (4) for vertex G; summing the differences between this and the other 10 values of $C_D(i)$ yields raw centralization $C_D = 20$. In a star network with 11 vertices, one vertex has degree 10 while the 10 others have degree 1, so maximal degree centralization is 90; thus the normalized degree centralization value is 0.22. The corresponding normalized centralization values for shortest-path closeness and shortest-path betweenness are 0.27 and 0.43, so betweenness scores are somewhat more dispersed than the others.

Centrality in Valued Networks

While centrality measures are usually calculated using binary-valued data, versions of several exist for data that record variations in strength among edges, indexed by weights w_{ij}. Reflection centrality $C_R(i)$ and β-centrality $C_\beta(i)$ may be calculated directly after substituting the weights w_{ij} for the corresponding binary network variables x_{ij} in the formulas for those measures. Opsahl et al. (2010) suggest the total strength of a vertex's connections as a parallel to degree centrality for valued data:

$$C_D^W(i) = \sum_{j=1}^{N} w_{ij}$$

Developing closeness and betweenness centrality measures for valued network data require a distance measure d_{ij}^W that takes the edge weights into account. One algorithm for doing so defines the 'weighted length' of a valued edge as the reciprocal of its weight, i.e., $1/w_{ij}$, and that of a valued path as the sum of the weighted lengths of the edges composing it. For example, the weighted length of a path including two edges having weights of 2 and 4 is $1/2 + 1/4 = 0.75$, less than that of a single-edge path with weight 1. The distance d_{ij}^W between two vertices then may be defined as the minimum weighted length of any valued path connecting them. A closeness centrality measure for valued data analogous to $C_C(i)$ follows:

$$C_C^W(i) = \frac{1}{\sum\limits_{\substack{j=1\\(i\neq j)}}^{N} d_{ij}^W}$$

Constructing a betweenness measure $C_B^W(k)$ for weighted data begins by defining g_{ij}^W as the number of minimum weighted length paths connecting vertices i and j, and $g_{ij}^W(k)$ as the number of those paths that include vertex k as an intermediary. Then

$$C_B^W(k) = \sum_{i=1}^{N}\sum_{j=i+1}^{N} b_{ij}^W(k) = \sum_{i=1}^{N}\sum_{j=i+1}^{N} \frac{g_{ij}^W(k)}{g_{ij}^W}$$

Flow-betweenness centrality (Freeman et al., 1991) is a distinct medial measure for valued data. It assesses a vertex's importance to a network's capacity for transmitting information or resources. Flow between two vertices may proceed simultaneously along multiple channels (not only shortest paths) that share no edges. The capacity of an individual edge is its weight w_{ij}, while that of an indirect path is the minimum weight of any edge it includes. The potential flow (f_{ij}) between vertices i and j sums the capacities of one or more edge-distinct paths; the flow between i and j that must pass through an intermediary vertex k is denoted $f_{ij}(k)$. A vertex's flow-betweenness centrality is the ratio of the sums of these quantities over all pairs of vertices:

$$C_{FB}(k) = \frac{\sum_{i=1}^{N}\sum_{j=i+1}^{N} f_{ij}(k)}{\sum_{i=1}^{N}\sum_{j=i+1}^{N} f_{ij}}$$

$C_{FB}(k)$ gives the extent to which the total flow between other vertices in a network depends on a particular vertex k. Koschützki et al. (2005) refer to it as a 'vitality' measure because it gives the proportional reduction in total network flow to be anticipated if vertex k (and all edges involving it) were to be removed from a network.

Centrality in Directed Networks

Many networks involve relationships in which something moves *from* one party *toward* another, and such flows need not be two way. Sentiments such as liking or admiration may be unrequited, for instance; likewise, authority relationships are usually one directional. 'Directed' data arrays represent networks of such relationships.

In directed networks, relationships (known as *arcs*) originate at one entity and end at another (e.g., John reports to Sue). A binary-valued network variable x_{ij} is 1 if an arc from origin vertex i to destination vertex j exists, and otherwise 0; a reciprocal arc from j to i may, but need not, be present. A network with N vertices may contain as many as $N(N-1)$ arcs. Weights w_{ij} may accompany arcs; here we consider binary data, however.

Definitions of indirect connectivity in directed networks take the orientation of arcs into account. A *directed path* is a sequence of concatenated and consistently oriented arcs leading from an origin vertex to a destination one, in which no vertex or arc appears more than once. The geodesic distance from one vertex to a second (d_{ij}) need not equal that from the second to the first (d_{ji}) in a directed network.

Figure 2 displays a directed, binary-valued network including 11 vertices and 20 arcs. Arrowheads indicate the orientation of arcs; an arc runs from vertex 5 to vertex 8, for example. Double-headed lines (e.g., that between vertices 1

Figure 2 A directed, binary network. Constructed using igraph (Csárdi, Gábor, Nepusz, Tamás, 2006. The igraph software package for complex network research. InterJournal Complex Systems 1695).

and 6) denote relationships with arcs in both directions. A directed path of length 3 from 7 to 8 (via 3 and 5) exists, but no directed path from 8 to 7 is present, so the geodesic distance d_{87} is infinite.

Radial centrality measures for directed networks typically distinguish a vertex's importance as an origin of relationships from that as a destination. Vertices that score high as destinations are often deemed to be prestigious or to hold high status. This leads, for example, to separate measures of outdegree (O) and indegree (I) centrality:

$$C_{\mathrm{D}}^{O}(i) = \sum_{j=1}^{N} x_{ij} \quad \text{and} \quad C_{\mathrm{D}}^{I}(i) = \sum_{j=1}^{N} x_{ji}$$

Outdegree centrality – the number of outgoing arcs from a vertex – is sometimes termed 'expansiveness,' while indegree centrality – the number of incoming arcs – is known as 'popularity.'

Likewise, distinct outgoing and incoming geodesic distances lead to separate out-closeness and in-closeness measures. Counterparts to shortest-path closeness are

$$C_{\mathrm{C}}^{O}(i) = \frac{1}{\sum\limits_{\substack{j=1\\(i\neq j)}}^{N} d_{ij}} \quad \text{and} \quad C_{\mathrm{C}}^{I}(i) = \frac{1}{\sum\limits_{\substack{j=1\\(i\neq j)}}^{N} d_{ji}}$$

Analogous pairs of measures can be constructed using other distance concepts, including random-walk distance or eccentricity.

A generalization of reflection/eigenvector centrality also leads to separate outgoing and incoming measures of a vertex's importance. It defines a central incoming vertex as one targeted by arcs emanating from central outgoing vertices, and a central outgoing vertex as one that sends arcs toward central incoming vertices. Incoming reflection centrality is proportional to a sum of incoming arcs, weighted by the outgoing reflection centrality of their sources:

$$C_{\mathrm{R}}^{I}(i) \sim \sum_{j=1}^{N} x_{ji} C_{\mathrm{R}}^{O}(j)$$

Similarly, outgoing reflection centrality is proportional to a sum of outgoing arcs, weighted by the incoming reflection centrality of their targets:

$$C_{\mathrm{R}}^{O}(i) \sim \sum_{j=1}^{N} x_{ij} C_{\mathrm{R}}^{I}(j)$$

Kleinberg (1999) used these measures to identify important vertices in citation networks linking Web pages. 'Authorities' have high $C_{\mathrm{R}}^{I}(i)$ values; they are prominent sources of knowledge about a topic. 'Hubs,' on the other hand, provide portals leading to authorities; they have high $C_{\mathrm{R}}^{O}(i)$ values.

Incoming reflection centrality scores may be found by calculating reflection centrality $C_{\mathrm{R}}(i)$ for a valued 'cocitation' network with elements

$$s_{ij}^{I} = \sum_{k=1}^{N} x_{ki} x_{kj}$$

that give the number of sources that send arcs to both vertices i and j. Outgoing reflection centrality scores can be obtained via similar calculations for a valued network with elements

$$s_{ij}^{O} = \sum_{k=1}^{N} x_{ik} x_{jk}$$

giving the number of common destinations for arcs that emanate from both vertices in a pair.

In directed networks, a vertex may lie between two others in one direction, but not the other. Medial measures take account of this by counting betweenness for directed pairs of vertices. A directed version of shortest-path betweenness, for example, is

$$C_{\mathrm{B}}(k) = \sum_{i=1}^{N} \sum_{j=1}^{N} b_{ij}(k) = \sum_{i=1}^{N} \sum_{j=1}^{N} \frac{g_{ij}(k)}{g_{ij}}$$

where g_{ij} and $g_{ij}(k)$ refer to the number of shortest directed paths linking vertices i and j, and the number of those including vertex k as an intermediary.

Table 2 shows that vertices 6 and 11 in Figure 2 have the highest outdegree, 4; likewise, they also have relatively high outgoing closeness and reflection (hub) centrality. Because infinite geodesic distances separate many pairs of vertices in Figure 2, closeness scores in Table 2 were calculated using Newman's (2010) alternate definition. Vertex 1 has the highest outgoing reflection (hub) centrality because it sends arcs to two highly authoritative vertices, 3 and 6. The latter two vertices have the highest indegree and in-closeness. Vertex 6 ranks highest in terms of betweenness, positioned such that it can control the equivalent of 25.5 geodesics connecting other vertices; its normalized betweenness is 0.28.

Table 2 Selected centrality scores for vertices in **Figure 2**

Centrality in Two-Mode Networks

A special but common type of network involves relationships between two distinct 'types' of entities. Often these are affiliations of individuals with groups, e.g., memberships of directors on corporate boards, or of nations in international treaties. In these '*two-mode*' networks, an entity's type is fundamental: entities of a given type are never linked to one another directly, only indirectly via their shared affiliations with entities of the other type.

A two-mode network includes N_A vertices of type A, indexed from 1 to N_A, and N_B vertices of type B, indexed from $N_A + 1$ to $N_A + N_B = N$. Relationships x_{ij} in such networks are usually binary-valued and undirected. All relationships (edges) link vertices of different types:

$$x_{ij} \equiv 0, \text{ if } i \le N_A \text{ and } j \le N_A, \text{ or if } i > N_A \text{ and } j > N_A$$

The degree, closeness, betweenness, and reflection/eigenvector vertex centrality measures for undirected two-mode networks can be calculated as discussed earlier. Constructing normalized measures requires care, however: maximum possible centrality values depend on vertex type, and must take into account the restriction that no edges can connect vertices of the same type. For degree centrality, for example, a vertex of type A can be linked to all N_B type B vertices (not all $N - 1$ other vertices), while one of type B can be linked to as many as N_A type A vertices. So vertex type determines the appropriate adjustment factor used in obtaining a normalized degree centrality measure:

$$C'_D(i) = \frac{\sum_{j=N_A+1}^{N_A+N_B} x_{ij}}{N_B}, \text{for } i \le N_A [\text{type A vertices}], \text{and}$$

$$C'_D(i) = \frac{\sum_{j=1}^{N_A} x_{ij}}{N_A}, \text{for } i > N_A [\text{type B vertices}]$$

Everett and Borgatti (2005) give similar adjustments for normalized closeness and betweenness centrality in two-mode networks.

Figure 3 A two-mode network. Constructed using igraph (Csárdi, Gábor, Nepusz, Tamás, 2006. The igraph software package for complex network research. InterJournal Complex Systems 1695).

Reflection centrality scores for the distinct types of vertices in two-mode networks are interrelated in the same way that incoming and outgoing reflection scores are in directed networks. Vertices of one type acquire high reflection centrality via edges that connect them to high-centrality vertices of the other type:

$$C_R(i) \sim \sum_{j=N_A+1}^{N_A+N_B} x_{ij} C_R(j), \text{for } i \le N_A [\text{type A vertices}], \text{and}$$

$$C_R(i) \sim \sum_{j=1}^{N_A} x_{ij} C_R(j) \text{ for } i > N_A [\text{type B vertices}]$$

[a]Scaled such that sum of squared scores is 1.

A type A vertex is central when it is related to central type B vertices, and vice versa.

Figure 3 displays a two-mode network including 11 vertices of type A (indicated by numbers and circles) and 7 vertices of type B (indicated by letters and squares). All 31 edges connect vertices of different types. **Table 3** reports several centrality measures for this network. Among the type A vertices, 2, 7, and 11 are most central; vertex 11 has the highest normalized degree centrality, 0.71. Vertex T is the most central type B vertex, with normalized degree centrality 1.0; vertex X is next. The less central type B vertices near the periphery of **Figure 3** are affiliated with smaller subsets of type A vertices.

Conclusion

Beyond the measures of network centrality covered here are numerous others. Among these are indices of degree, closeness, and betweenness centrality for sets of two or more vertices (Everett and Borgatti, 2005). A distinct approach (e.g., Gómez et al., 2003) synthesizes network analysis and game theory, conceiving of a vertex's importance as the incremental value accruing when the structure of a network delimits opportunities for exchange or coalition formation. Centrality then depends on both network structure and the rules and payoff structure of a particular game.

Though conceptually distinct from one another, the various centrality measures discussed here tend to assign similar relative scores to vertices in many empirical instances, as illustrated in **Tables 1–3**. Some definitional dependencies among them exist: a vertex with high degree has a large number of length-1 geodesics linking it to others, for example; its average distance to others tends to be lower, and it hence tends to score higher in terms of closeness. Likewise, because a vertex must have degree of at least 2 in order to be between any pairs of others, degree and betweenness tend to be associated. Notwithstanding this, the different measures are not interchangeable: they are sensitive to different features of structural importance within a network.

When selecting a centrality measure from among the many available, the conceptual or theoretical purpose to be served – that is, the way in which a particular centrality measure corresponds to one's notion of (e.g.,) power, status, or influence – is a vital consideration. One important aspect of this is the basic distinction between radial measures of a vertex's capacity to access others and medial measures of its potential as a transmitter. Friedkin (1991), for example, derives measures resembling reflection/eigenvector, closeness, and betweenness centrality from a single process model of social influence; these tap distinct components of a vertex's influence. As well, a study's substantive setting and the nature and content of measured relationships among entities merit attention. Borgatti (2005) offers some guidance here based on the match between centrality measures and different assumptions about the kinds of flow processes taking place within a network structure.

Network Models of Tasks

Richard Schweickert, Purdue University, West Lafayette, IN, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Processes executed in performing a task can often be represented in a network. Each process requires time and has a probability of producing correct output. When networks are used in scheduling, process durations and organization are known. The network is used to calculate the task completion time. A psychologist has the inverse problem. The time to complete the task is observed. The problem is to infer the organization of the mental processes and their durations. A similar inverse problem arises if accuracy is observed. These inverse problems can be solved by manipulating experimental factors that selectively influence processes.

Network Models of Tasks

A person performing a task such as judging the emotion portrayed in a face carries out processes such as perceiving, deciding, and responding. The processes can often be represented in a task network, as in Figure 1. Vertex o is the start of the task (typically, stimulus presentation). Each arc represents a process. Associated with each arc is the duration of the process and the probability the process produces the correct output for the input given. The processes leaving a vertex all begin when a release condition is met by the processes entering the vertex. A process leaving an AND gate vertex begins execution when all the processes entering the vertex are completed. A process leaving an OR gate vertex begins execution as soon as any process entering the vertex is completed. Vertex r is the end of the task, typically, response execution.

Representation of Processes

The bar chart (or Gannt chart) in Figure 2 illustrates a model of the psychological refractory period (Davis, 1957; Pashler, 1998). Two stimuli, o_1 and o_2, are presented, requiring responses r_1 and r_2, respectively. For stimulus o_1, perceptual processing is denoted as a_1, response selection is denoted as b_1, and motor preparation is denoted as c_1. Processes for stimulus o_2 are denoted analogously. The interval between the onsets of the stimuli, the stimulus onset asynchrony, is denoted as SOA. The length of the bar representing a process indicates its duration. The arrow from the end of b_1 to the beginning of b_2 indicates that b_1 must be completed before b_2 can start, in accordance with the single channel hypothesis that only one response can be selected at a time.

Figure 1 A task network. This is a Wheatstone bridge.

Process durations are easily apprehended from the bar chart, but precedence relations between the processes are not. The bar chart in Figure 2 can readily be converted to a task network, as in Figure 3. Precedence relations are more easily seen in the task network, but visual representation of the process durations is lost.

We begin by discussing the use of a network to represent time; later we discuss accuracy. In the theory of scheduling a task, network is used to calculate the time required to complete the task from known durations of directed paths through the network. A directed path from a vertex u to a vertex z is formed by starting at u, going along an arc leaving u to another vertex v, and so on, ending at the vertex z. There is no directed path from the starting vertex of a process to itself, that is, no directed path is a cycle. Hence, a task network is a directed acyclic network. The duration of a path is the sum of the durations of all the arcs on it. If the vertices are AND gates, the network is called a PERT (Program Evaluation and Review Technique) network, and the longest path from o to r is called the critical path. The time to complete the task is the duration of the critical path. If the vertices are OR gates, the time to complete the task is the duration of the shortest path from o to r. Usually

Figure 2 Bar chart for a double stimulation task.

Figure 3 Bar chart in Figure 2, redrawn as a task network.

in tasks performed by humans, the time from stimulus onset to response execution is the reaction time.

Constructing the Network

One way to construct a network representing the processes in a task is through task analysis, that is, systematically observing someone perform the task and diagramming those processes that can be observed and those that can be inferred as logically necessary. Durations of observable processes can be found by timing them, and estimates of durations of unobservable processes, such as switching attention to a tone, can sometimes be found in the literature.

A successful example is a task analysis done by Gray et al. (1993). While new machines for telephone operators were under construction, videos of operators using the old machines were studied. PERT networks were drawn for performance of various tasks with the old machines and with the planned new machines. The new machines were designed to make certain individual processes faster. However, the PERT network analysis predicted that the overall time required for tasks with the new machines would be longer than with the old machines. The reason was that the faster processes were not always on the critical path for a task, so speeding them up did not always shorten the completion time for the task. On the other hand, with the new machines certain processes were added to the critical path, thus increasing the time needed to complete the task. When the actual new machines were installed, tasks indeed required more time.

The processes involved in a task are often unobservable mental processes. The analyst faces an inverse problem. The completion time of the task may be known under various conditions, and the problem is to infer the form of the task network and the durations of the processes. The key is to find experimental factors that selectively influence processes, a technique pioneered by Sternberg (1969) in his additive factor method. Suppose one experimental factor (say, degrading stimulus quality) prolongs one process, leaving the others unchanged. Suppose another experimental factor (say, increasing response complexity) prolongs another process, leaving the others unchanged. Suppose the processes required for the task are executed one after the other, in series. Then the increase in completion time, produced by prolonging both processes, will be the sum of the increases produced by prolonging them individually. This prediction can easily be tested. If it is satisfied, a network with processes in series can account for the data.

When process durations are stochastically dependent, factors influencing processes can have unexpected consequences (Townsend and Thomas, 1994). Complications arise when a factor prolongs a process p, and the duration of process p is correlated with the duration of a process q; then the duration of process q is changed when the level of the factor is changed. Nonetheless, processes whose durations are dependent on one another can be selectively influenced by factors producing well-behaved effects. A crucial assumption is needed when the process durations are conditionally independent, that is (for two processes), the duration of process p is independent of the duration of process q given a value of a third random variable c. For details, see Dzhafarov (2003).

Prolonging a Single Process

If all the processes are in series, two factors selectively influencing different processes will have additive effects on reaction time. But suppose some processes are concurrent with others. Then, when a process p is prolonged by an amount Δp, the response time need not increase by Δp. To see this, suppose all vertices are AND gates. In Figure 1 process x can be prolonged by up to 2 units without increasing the response time. The longest time by which a process p may be prolonged without delaying the response is called the total slack for p, denoted $s(p, r)$. The first $s(p, r)$ units of the prolongation are used to overcome the total slack for p, and the remainder increases the response time. Let $T(0)$ denote the response time when no processes are prolonged and let $T(\Delta p)$ denote the response time when process p is prolonged by Δp. Then $T(\Delta p) = T(0) + \max\{0, \Delta p - s(p, r)\}$. The numbers on the arcs in Figure 1 can be considered values of the process durations for a single trial in an experiment. If the process durations and the prolongation of p are random variables, then, taking expected values, $E[T(\Delta p)] = E[T(0)] + E[\max\{0, \Delta p - s(p, r)\}] \geq E[T(0)]$.

To see how slack arises, consider the SOA in Figure 2. Suppose processes a_1 and b_1 have long durations. Then increasing the duration of the SOA a little will have no effect on the time at which the response to the second stimulus is made.

Prolonging Two Processes

When two factors selectively influence two different processes, the effects on response time depend on how the processes are related. Relations between processes are determined by directed paths. If there is a directed path from the head of a process p to the tail of a process q, then p must be completed before q can start, and p precedes q. Processes p and q are called sequential if either p precedes q or q precedes p. If processes p and q are not sequential, they are concurrent. Concurrent processes p and q can be executed in any order. That is, p and q may be executed simultaneously, p may be completed before q starts, or q may be completed before p starts.

Assume (1) no process precedes itself (irreflexivity) and (2) if a process p precedes a process q, and process q precedes a process t, then p precedes t (transitivity). In other words, precedence is a partial order.

Let the response time when p is prolonged by Δp and q by Δq be denoted $T(\Delta p, \Delta q)$; the notation is analogous for other conditions. Suppose p and q are concurrent processes. Then the response time when both p and q are prolonged is the larger of the response time when p is prolonged and the response time when q is prolonged, that is,

$$T(\Delta p, \Delta q) = \max\{T(\Delta p, 0), T(0, \Delta q)\}$$

Considering expected values,

$$E[T(\Delta p, \Delta q)] = E[\max\{T(\Delta p, 0), T(0, \Delta q)\}]$$

A quantity sensitive to the relation between two prolonged processes is the interaction contrast (Schweickert, 1978). For concurrent processes x and y, this quantity is negative or 0, that is,

$$E[T(\Delta p, \Delta q)] - E[T(\Delta p, 0)] - E[T(0, \Delta q)] + E[T(0, 0)] \leq 0$$

Suppose p and q are sequential processes. When p and q are both prolonged the response time is a complicated function of their respective prolongations, Δp and Δq. When the prolongations are long enough to overcome the relevant slacks, the interaction contrast takes the following simple form,

$$E[T(\Delta p, \Delta q)] - E[T(\Delta p, 0)] - E[T(0, \Delta q)] + E[T(0, 0)] \\ = E[s(p, r) - s(p, q)]$$

Here $s(p, q)$ is the slack from p to q, the longest time by which p can be prolonged without delaying the start of process q. The quantity on the right hand side of the above equation is an important parameter of the network, called the coupled slack between p and q, denoted as $E[K(p, q)] = E[s(p, r) - s(p, q)]$. Its use has been described later.

Ordinarily, the total slack for p is greater than or equal to the slack from p to q, and consequently the interaction contrast for sequential processes is zero or positive. The one exception is when x and y are on opposite sides of a Wheatstone bridge, as in Figure 1. For this network, $s(x, r) = 2 \leq s(x, y) = 4$, and the interaction contrast is negative. Then processes on opposite sides of a Wheatstone bridge can mimic concurrent processes, because both arrangements of processes lead to negative interaction contrasts. The main difference is that for the Wheatstone bridge, when the prolongations are long, the value of the interaction contrast does not change as the prolongations become still longer. This is not true for the interaction contrast corresponding to concurrent processes.

When vertices are OR gates, the main difference is a reversal of signs. For concurrent processes, the interaction contrast is positive. For sequential processes not on opposite sides of a Wheatstone bridge, the interaction contrast is negative or zero. For sequential processes on opposite sides of a Wheatstone bridge, the interaction contrast is positive.

Information beyond that provided by interaction contrasts of mean reaction times can be obtained from interaction contrasts of their cumulative distribution functions (or, equivalently, survivor functions). For details, see Townsend and Nozawa (1995) and Schweickert et al. (2012).

Task Network Inference

By analyzing results of selectively influencing processes one at a time and in combinations, one obtains information about how processes are arranged in the network. As an example, consider the data in Table 1, from an experiment by de Jong (1993). Two stimuli were presented to the subject on each trial, a tone and a letter. The tone was either low or high pitched, and the subject responded to it with the left hand, one button to indicate the low-pitched tone and another button to indicate the high-pitched tone. The letter was either a B or a D, and the subject responded to it by pressing a button with the right hand in one condition and by pressing a pedal with the left or the right foot in another condition. In some blocks of trials the subject pressed one button (or pedal) for B and another button (or pedal) for D, so there were two alternatives for the response to the letter. In other blocks of trials, the subject pressed the same button (or pedal) for both B and D, so there was only one response alternative for the letter. The interval between presentation of the tone and of the letter (the SOA) was 25, 250, or 800 ms. Table 1 gives the mean time at which the response to the letter was made, measured from the onset of the tone. (If we let RT2 denote the interval between the presentation of the letter and the response to the letter, then Table 1 gives RT2 + SOA.) The times were read from Figure 4 of de Jong (1993). The reader is referred to the paper for further data and to Schweickert et al. (2012) for further analysis; just enough is presented here to work out the example.

Table 1 Mean RT2 + SOA in de Jong's (1993) experiment 2

		SOA	
Response 2 alternatives	*Response 2 limb*	*25*	*800*
2	Foot	672	1224
2	Hand	587	1138
1	Foot	545	1071
1	Hand	529	1000

All times are in milliseconds.
Data read from Figure 4 of de Jong, R., 1993. Multiple bottlenecks in overlapping task performance. Journal of Experimental Psychology: Human Perception and Performance 19, 965–980.

The data give clear evidence that there is slack for the SOA. From the bottom row of the table, when the SOA was increased from 25 to 800 ms, an increase of 775 ms, the time to respond to the letter increased by only 471 ms.

There are three factors, SOA, the number of response 2 alternatives, and the response 2 limb. Suppose these selectively influence processes SOA; central processing, b; and motor preparation, c, respectively.

Suppose all the prolongations are long enough to overcome the relevant slacks. Then the coupled slack from SOA to c is

$$K(\mathrm{SOA}, c) = T(\Delta\mathrm{SOA}, 0, \Delta c) - T(\Delta\mathrm{SOA}, 0, 0) - \mathrm{T}(0, 0, \Delta c) \\ + T(0, 0, 0) \\ = 1071 - 1000 - 545 + 529 = 55$$

The expression $T(0, 0, \Delta c)$ denotes the observed mean time for the response when process c is prolonged but no other process is; other expressions are analogous.

The coupled slacks for the other two pairs of processes can be calculated in a similar manner. They are

$$K(\mathrm{SOA}, b) = 80 \text{ and } K(b, c) = 69$$

From these coupled slacks the time at which the response is made when all three processes are prolonged can be predicted. (Derivation is beyond the scope of this article, see Schweickert, 1978.) The predicted value is

$$T(\Delta\mathrm{SOA}, \Delta\mathrm{b}, \Delta\mathrm{c}) = T(\Delta\mathrm{SOA}, 0, 0) + K(\mathrm{SOA}, b) + T(0, \Delta b, 0) \\ + K(b, c) + T(0, 0, \Delta c) - 2T(0, 0, 0)$$

Figure 4 A task network.

The observed value (left hand side) is 1224. The predicted value (right hand side) is 1223. The observed and predicted values agree, support for the model. The outcome not only is a test but also provides information about the process order. There are three coupled slacks, but only two appear in the above equation. The coupled slack $K(\text{SOA}, c)$ is not used; it corresponds to the first and last of the three processes. It can be seen that process b is in the middle. One does not learn which of SOA or c is first from the equation, but logically SOA comes first.

In the example, something is learned about process order through parameter estimates. For a complicated task, it would not be practical to estimate all the parameters in the same experiment, and parameter estimates from different experiments may not be commeasurable. Fortunately, results from different experiments can be combined, without the need for precise parameter estimates. Because concurrent processes and sequential processes behave differently, one can determine which pairs of processes are concurrent and which are sequential. This information, possibly from different experiments, is sufficient for constructing a directed acyclic graph. One begins with a comparability graph in which each process is represented by a vertex, and two vertices are joined by an undirected edge if and only if the corresponding processes are sequential. All possible directed acyclic graphs can then be constructed with the transitive orientation algorithm (Golumbic, 1980).

Estimating Process Durations

Suppose process duration distributions are exponential or gamma, a reasonable assumption. Then the response time can be derived from an order-of-processing (OP) diagram (Fisher, Goldstein, 1983). Figure 4 gives a PERT network in which processes a and b are concurrent and both are followed by process c. Figure 5 gives the OP diagram made from the PERT network. Each vertex in the OP diagram is a state, in which certain processes are underway (upper list) and certain others are completed (lower list). The task begins with a and b both underway. In the following states, either a is completed or b is completed. Following either of these states, process c is underway. In the final state, process c is completed, and the task is finished.

Suppose processes have independent exponential distributions, with the mean of process a denoted as $1/\lambda_a$, and so on (λ_a is the rate of process a). The expected value of the response time can be read off the OP diagram. The first state is completed as soon as the faster of processes a and b is completed. The expected value of the minimum of two independent exponentially distributed processes is itself exponentially distributed, so the expected value of the duration of the first state is $1/(\lambda_a + \lambda_b)$. The probability that a is the first process to finish is $\lambda_a/(\lambda_a + \lambda_b)$. Because b is exponentially distributed, the expected value of the time remaining for b to complete given that a has already completed is $1/\lambda_b$. After repeated application of these rules, the expected value of the response time is the sum over all states of the expected duration of each state times the probability of reaching that state. For Figure 4,

$$E[T] = 1/(\lambda_a + \lambda_b) + [\lambda_a/(\lambda_a + \lambda_b)][1/\lambda_b] + [\lambda_b/(\lambda_a + \lambda_b)] \times [1/\lambda_a] + 1/\lambda_c$$

From the expressions for response times, one can use a nonlinear parameter estimation program to estimate the unknown rates, given the observations from enough conditions.

Figure 5 OP diagram for the task network of **Figure 4**.

A Generalization

OP diagrams can represent more general arrangements of processes than those in directed acyclic networks. Consider Figure 2. Suppose b_1 and b_2 are sequential, but either could be executed first. The situation cannot be represented with a single directed acyclic network, but can be represented with one OP diagram.

Processing Tree Representations

The accuracy of a task is often described through a processing tree model (for review see Batchelder and Riefer, 1999). In these models, a process is represented by a vertex and the outcomes of the process by arcs descending from the vertex; see Figure 6. Associated with each arc is the probability that the outcome it represents occurs. When the task starts, processing begins at the root, a vertex with no arc entering it. One of the outcomes of this process occurs, and the arc corresponding to this outcome is followed to its ending vertex. The process at this vertex is executed, one of its outcomes occurs, and so on, until a vertex with no descending arc is reached. Such a vertex is called a terminal vertex. Each terminal vertex is associated with a type of response, for example, a correct or wrong response. When a terminal vertex is reached, a response of its type is made.

A response of a certain type is made when a path is followed from the root to a terminal vertex for this response type. The probability of such a path is the product of the probabilities associated with the arcs on the path. The probability of a response of a certain type is the sum of the probabilities of all the paths resulting in that type of response.

The Inclusion/Exclusion Paradigm

A popular use of processing trees is to model the inclusion/exclusion paradigm developed by Jacoby (1991). Typically in the paradigm a subject is presented with a list of words to memorize, presented, say, visually. Then the subject is presented with another list to memorize, presented, say, auditorily. A recognition test follows. On each trial a test word is presented. Subjects in the inclusion condition are instructed to

Figure 6 Processing trees for the inclusion/exclusion paradigm.

say the word is old if it appeared in either list. Subjects in the exclusion condition are instructed to say the word is old only if it appeared in the second list.

According to the model, subjects in the exclusion condition say a word is old in two ways. One way is that they vividly recall learning the word, a state called recollection. In that case they will remember the way the word was presented. The other way they will say a word is old is if they do not recollect learning it, but the word looks familiar. Let R denote the probability of recollecting a word and let F denote the probability a word looks familiar, given it was not recollected.

Consider a test word originally presented in list 2. A subject in the exclusion condition recollecting it will remember the way it was presented, conclude it was not presented in list 1, and say new. The only way a subject in the exclusion condition would say a test word from list 2 is old is if the subject does not recollect the word, but the word seems familiar. The probability is $(1-R)F$; see Figure 6.

A subject in the inclusion condition will say a word is old if the subject recollects learning it, or if the subject does not recollect learning it but the word looks familiar. A subject in the inclusion condition will say a word from list 2 is old with probability $R+(1-R)F$. The two equations above can be solved for the two unknown quantities, R and F. (They are not uniquely determined.)

To test the model, experimental factors are manipulated that are expected to change one parameter but not the other, that is, to selectively influence recollection or familiarity. As an example, subjects in a divided attention condition learned words while concurrently performing a distracting task. Subjects in a control condition did not perform the distracting task. The distracting task was expected to change the probability R of recollection, but not the probability F that a word would look familiar, and this was indeed the result.

Tree Inference

An investigator often begins by specifying a plausible processing tree for a task, guided by task analysis and previous findings in the literature. The model is tested by estimating parameters and evaluating goodness of fit. Another approach, tree inference, is to construct a processing tree by examining the effects of factors thought to selectively influence processes in the tree (Schweickert and Chen, 2008). Consider the case where there are two response types, say, correct and wrong. Suppose the investigator manipulates two experimental factors. Consider the hypothesis that the subject performs the task using a processing tree and each factor changes parameters on arcs that descend from a single vertex, a different vertex for each factor.

There are two possibilities for the two vertices. One possibility is that there is no path from the root to a terminal vertex for a correct response that passes through the two vertices; the other possibility is that there is such a path. Let i be a level of one factor and j be a level of the other. A particular processing tree with no path that passes through the two vertices gives the probability of a correct response as

$$p_{ij} = ax_i + (1-a)y_j$$

This tree is called the standard tree for unordered processes.

A particular processing tree with a path that passes through the two vertices gives the probability of a correct response for the combination of factor levels i and j as

$$p_{ij} = w_i + x_i y_j$$

This tree is called the standard tree for ordered processes. (It is for the case when the factor with levels indexed by i selectively influences the vertex that comes first on the path from the root. For the reverse order, one would switch i and j in the above equation.)

These two trees can easily be distinguished with data. Given data, parameters for the first equation can be found if and only if the factors have additive effects on the probability of a correct response. Parameters for the second equation can be found if and only if the following two conditions hold.

The levels j can be numbered in order so that if $j > j'$ then for every level i, $p_{ij} \geq p_{ij'}$.

There exist levels i^* and j^* such that for every i there is a number $r_i \geq 0$ with $p_{ij} - p_{ij^*} = r_i(p_{i^*j} - p_{i^*j^*})$.

If neither standard tree fits the data, then there exists no processing tree in which each factor selectively influences a parameter on arcs descending from a single vertex. Moreover, suppose the subject employs an arbitrary processing tree in which each factor selectively influences a parameter on arcs descending from a single vertex. Then for every combination of levels of the factors the processing tree used by the subject makes exactly the same predictions as one of the two standard trees.

Abstract

Network theory and analysis have played a prominent role in the field of organization science for more than six decades. Previous articles of the organizational networks literature have discussed the attributes, antecedents, and consequences of networks. Our article focuses on the organizational functions of networks. Specifically, we discuss how networks enable exploration, exploitation, and organization.

Network is a valuable concept in the natural, biological, social, and engineering sciences. It has been used to study a wide variety of topics including gene sequencing, terrorist cells, computer software, job search, organizational structure and innovation, and the global economy (Barabási, 2002). A network is a set of *actors* (nodes) and the *ties* (links) between them. In a social network, an actor can be an individual, group, firm, organization, or national government, so the scope and complexity of a network analysis can be considerable (cf Castells, 2010; Johnson, 2014). Network analysis has been utilized in the organization sciences for more than six decades (Simmel, 1950; White, 1963), and arguably it has attained the status of a paradigm (Kuhn, 1962). In this article, we focus on organizational networks and examine them from a functional perspective – how they enable organizations to explore, exploit, and organize.

Properties of Networks

Network research has examined the attributes, antecedents, and consequences of networks (for reviews see Borgatti and Foster, 2003; Borgatti and Halgin, 2011; Brass et al., 2004). Networks have tie properties and structural properties. Ties are characterized by the type of content they carry, such as goods, information, or moral support, and by their strength. Tie strength is a function of various factors, including time and reciprocity, and tie strength affects how a network operates. Strong ties provide support among actors and enable the transfer of rich information and tacit knowledge. Weak ties, on the other hand, are sources of diverse resources and novel information (Granovetter, 1973).

The basic network structure is a dyad: two actors connected by a common tie. Dyads are the building blocks of larger network structures. A triad consists of three actors and at least two ties (Simmel, 1950). If each actor in the triad is directly connected – that is, the triad consists of three dyads – then the triad is closed. A closed triad confers the benefit of trust among actors in the network. When a triad is open, Simmel (1950) called the actor with ties to the two unconnected actors the *tertius gaudens*, which means 'the third who benefits'. A *tertius gaudens* can serve as a broker between actors and may benefit from playing them off against each other, thereby becoming powerful within the network. Triads, in turn, are the building blocks of clusters, which are agglomerations of densely connected actors.

Networks are unbounded in the sense that everyone is directly or indirectly linked to everyone else. Researchers, therefore, usually study particular subsets of networks. An ego network is the network surrounding a focal actor. The ego network is a source of both opportunities and constraints. Three important ego-network measures are network size, actor centrality, and network density. Centrality is a measure of the importance of an actor in a network, and centrality measures differ in the weights given to direct and indirect ties. Centrality confers status, influence, and access to resources in the network. Density is the ratio of actual to possible ties among a set of actors. High density in an ego network provides the focal actor with closure benefits, such as trust and shared understanding, and it constrains opportunistic actions and reduces costly monitoring processes. As a result, a closed network provides a basis for cooperation and collective action.

Large networks consist of interconnected clusters. Such networks are characterized by their degree of centralization, which measures the extent to which there are central actors in the network; degree of clustering, which measures the extent to which triads in a network are closed; and average path length, which measures the average number of links in the shortest path between any two actors in the network. Degree of clustering and average path length are used to characterize how actors in large networks have access to closure benefits as well as the benefits that come from network integration, such as the rapid diffusion of knowledge and information. Small worlds are non-centralized, clustered networks with short average path lengths (Milgram, 1967; Watts, 1999). Small worldliness can increase network performance by allowing resources to develop locally and flow efficiently between the clusters (Uzzi and Spiro, 2005).

Network size and structure are determined by the interaction of technological, social, and institutional factors. Katz and Shapiro (1985) showed that expectations of future network size influence potential actors' decisions to join the network. Moreover, a network's initial properties create path dependence in both current network attractiveness and the actors' expectations about future network size (Arthur, 1989). Finally, the actions of individual actors, guided by 'generative rules' (Kogut, 2000) concerning interaction with others, affect both network size and structure. Thus, as the network evolves, its size and

 http://dx.doi.org/10.1016/B978-0-08-097086-8.73107-2

shape result from past decisions, future expectations, and generative rules.

Functions of Networks

In order to survive and prosper, organizations need to continuously learn and adapt. Networks enable organizations and their members to both shape and adapt to their environments. Organizations make ongoing decisions about *exploring*, the development of new knowledge, capabilities, and opportunities (March, 1991); *exploiting*, the diffusion, utilization, and refinement of existing knowledge, capabilities, and operations (March, 1991); and *organizing*, the accumulation and arrangement of resources into an activity system (Miles and Snow, 1978). Those decisions affect both the short-term performance and the long-run survival of organizations. Exploring, exploiting, and organizing are three core activities of organizations that are facilitated by various types of networks and network processes (Lazer and Friedman, 2007).

Exploring

Organizations arise in response to opportunities. Getting organized implies the exploration of opportunities and the development of capabilities to pursue them. Organizations learn from search and experimentation, and they require absorptive capacity (Cohen and Levinthal, 1990) in order to develop their capabilities. Networks are sources of information, opportunities, knowledge, and capabilities, and different types of network ties and structures play complementary roles in exploration. See **Table 1** for a summary of how networks enable organizations to explore.

Table 1 How networks enable exploration

Network attribute	*Function*
Weak ties	Low-intensity, sporadic relationships support exploration by providing access to novel information and diverse resources.
Strong ties	Intimate, long-lasting relationships facilitate the transfer of rich information and tacit knowledge, thus enabling joint problem solving. However, strong ties, coupled with path dependence, may inhibit sensitivity to disruptive innovations.
Structural hole	Brokers and others who span structural holes can enhance exploration initiatives because of their special access to information, knowledge, and resources. However, they can also divert exploration if they use their proprietary knowledge to engage in power plays or competitive maneuvering.
Centrality	Centrality provides more influence and greater access to information and resources.
Clustering	Direct connections among actors provide them with closure benefits such as shared norms, trust, and reciprocity.
Small worldliness	Dense clustering and short path lengths provide both diversity and closure benefits, and small worldliness positively affects creativity and innovation.

Weak Ties

Network actors typically have many weak ties, which connect them to a variety of other actors. Therefore, weak ties help to integrate social systems, providing access to novel information and diverse resources (Granovetter, 1973). Novel information is important to exploring such things as job opportunities, new technologies, and market opportunities.

Strong Ties

Strong ties facilitate the transfer of tacit or non-codified knowledge as well as the process of joint problem solving (Dyer and Nobeoka, 2000). Strong ties are embedded in social contexts such as long-term personal relationships among the actors in a network (Uzzi, 1996) or in relationships that the actors maintain with others outside the network (Granovetter, 1985). Strong ties facilitate exploration in complex, dynamic environments because of the bandwidth they provide for the transmission of rich, continuously changing information. However, strong ties may inhibit the exploration of discontinuous or disruptive innovations if they limit the scope of search processes. In such cases, firms may need to create new networks particularly suited to enabling discontinuous innovation.

Structural Hole

By extending the notion of an open triad to larger network structures, Burt (1992) developed the concept of a structural hole. A structural hole exists when an actor provides the only connection between other actors. Such an actor spans a structural hole and can benefit in two ways: (1) access to information, knowledge, and resources that are not universally held and (2) the ability to play actors, or groups of actors, off against each other in the competition for resources. The spanning of structural holes has been shown to affect careers and compensation, patenting, alliance performance, corporate acquisition performance, market entry choices, and firm financing and growth.

Centrality

Actors with high centrality have direct or indirect ties to a large portion of the network and therefore have links to otherwise unconnected actors. Overall, centrality provides greater access to resources (Cook and Emerson, 1978), and it can be parlayed into gains in individual performance and promotions, organizational innovations, and organizational performance.

Clustering

Degree of clustering affects actors' ability to monitor other actors' conduct and to sanction undesirable behavior. Actors create and maintain relationships within the network that provide them with collective closure benefits in the form of shared norms, trust, and reciprocity (Coleman, 1990). Clustered networks can transmit sensitive and rich information, mobilize collective action, and increase group innovation.

Small Worldliness

Both structural holes and closure are important attributes of social capital. Small world networks combine high clustering and short path lengths (Watts, 1999). A small world network may offer actors, as a collective, both diversity and closure

benefits, and small worldliness has been shown to positively affect creativity and innovation.

Exploiting

Exploitation is the diffusion, utilization, and refinement of existing knowledge, capabilities, and operations. Organizations benefit from both the internal and external diffusion of valuable innovations resulting from exploration. An organization benefits directly when customers adopt its products and services, and it benefits indirectly when knowledge and practices are adopted by employees and others with whom the organization interacts (Katz and Shapiro, 1986). Adopters are influenced by exposure to innovations from members of their professional and social networks, and successful diffusion is a function of resource value, the properties of sources, and the nature of adopters and their relationships with resource providers. Actors vary in their willingness and ability to transfer information and knowledge to others. Whereas early diffusion research focused on the attributes of early adopters and their networks (Rogers, 1962), recent studies have highlighted the importance to diffusion of actors' knowledge transfer capacity (Martin and Salomon, 2003), the degree of complementarity between the transmitter and the recipient (Aral and Walker, 2012), and the recipient's perception of the trustworthiness of the source (Szulanski et al., 2004). See **Table 2** for a summary of how networks enable organizations to exploit.

Tie Strength

Knowledge transfer, even within organizations, is difficult. Strong embedded ties are conducive to knowledge transfer because they are associated with trust and provide common frames of reference. Tie strength has been shown to be important in the transfer of product development knowledge, knowledge about market trends affecting firm survival, and best practices among units in multinational corporations.

Actor Position

Central actors have broad exposure to others and enjoy high status. As a result, information and innovations rapidly diffuse through their networks (Rogers, 1962). Their central position also gives them a 'vision advantage' (Burt, 2004), which favors their early adoption of innovations. However, Aral and Walker (2012) found that highly influential individuals tend not to be susceptible to influence by others. The diversity of information available to central actors may prevent information from reaching a threshold level required for adoption (Granovetter, 1978). Overall, central actors aid diffusion through their networks, but they are not necessarily good targets for the initial adoption of innovations.

Table 2 How networks enable exploitation

Network attribute	*Function*
Tie strength	Strong ties are conducive to knowledge transfer because of trust and common frames of reference.
Actor position	Central actors rapidly diffuse information and innovations. Because of their high status and central position, they are able to strongly influence other actors. However, central actors tend to be less susceptible to influence by others.
Connectivity	A moderate amount of connectivity is required for effective diffusion.
The network effect	For products, practices, or knowledge exhibiting a network effect, the benefits of joining a network increase with the adoption by others.

Connectivity

Studies of infectious diseases show that dense connectivity (multiple pathways among actors) increases spreading (Watts, 2004). However, dense connectivity has a different impact on the diffusion of innovations or information. When the quality of information is unknown, actors tend to seek social support for adoption, and if the actors are densely connected they may not be affected by new information because of competition from other sources. Therefore, diffusion takes place only when the connectivity of the network is 'neither too sparse nor too dense' (Watts, 2004: 261).

The Network Effect

The network effect refers to an actor's benefit from adoption being a function of the adoption by others. It arises in a number of situations such as the common adoption of institutions that enable societal specialization and integration, practices that facilitate knowledge sharing and collaboration, and new communication technologies. For products, practices, or knowledge exhibiting a network effect, the benefits of joining a network increase with the extent of adoption (Katz and Shapiro, 1985). A strong network effect can lead to winner-take-all situations (Shapiro and Varian, 1999) or fewer competing technologies in an industry (Katz and Shapiro, 1986).

Organizing

Organizing is the accumulation and arrangement of resources into an activity system. Activity systems are dynamic, with some parts of the system changing more frequently than others. An organization is a goal-directed system that must be controlled and coordinated. Networks facilitate control and coordination both within and across organizations. Tie properties as well as structural properties contribute to the organizing function. See **Table 3** for a summary of the organizing functions of networks.

Formal Ties

The formal structure of an organization is a network. Structure reflects how activities have been divided among organizational actors (division of labor), and activities are integrated through control and coordination mechanisms. Formal ties are the static, designed relationships typically shown in the organization chart, including reporting relationships and communication channels. Traditional organizational forms employ hierarchical mechanisms as the primary means of control and coordination. In hierarchical network structures, central actors have the authority to resolve conflicts at the periphery in part because they have a broader view of the organization and its environment. Hierarchies also allow higher-level actors to

Table 3 How networks enable organizing

Network attribute	*Function*
Formal ties	Formal relationships are official designations of the division of labor as well as the specification of authority and communication systems.
Informal ties	Boundary-spanning and other informal relationships complement formal ties to enhance control and coordination.
Dyadic interfirm ties	Dyadic interfirm linkages connect resources held by the respective organizations, creating a stock of relational assets.
Interlocking boards	Interlocking boards can serve four organizing functions: cooptation, resource access, control, and legitimation.
Multifirm ties	The main organizing benefits of the multifirm network are flexibility, the variety of capabilities that can be assembled, and the economies of scale and experience that can be leveraged in each activity.
Community	A community enables self-organization around shared goals and common resources. The community organizational model offers members the opportunity to collectively develop solutions and capabilities, allowing members to accomplish more than they could on their own.

control the goals and/or actions of subordinate actors in cascading principal–agent relationships. When the organization is strictly hierarchical, the network structure is centralized, with formal ties being mostly vertical. Less hierarchical organizations, such as those using matrix structures, create lateral ties to complement vertical ties.

Informal Ties

In addition to the formal organization, the informal organization is a supplementary mechanism that helps get tasks performed properly (Krackhardt and Hanson, 1993). Informal social networks are valuable in organizing the innovation process (Kleinbaum and Tushman, 2007). Boundary spanners (Tushman and Scanlan, 1981) – actors who operate at the boundaries of formal organizational units – help connect the organization to its environment by gathering, interpreting, and diffusing information within their informal networks.

Dyadic Interfirm Ties

A firm's critical resources, as well as the activities using and contributing to them, may span organizational boundaries. Dyadic interfirm linkages between boundary-spanning individuals connect resources held by their respective organizations, creating a stock of relational assets (Dyer and Singh, 1998). The primary function of dyadic ties is to increase the efficiency and effectiveness of network actors by linking their activities and leveraging their relational assets.

Interlocking Boards

Corporations are required by law to have a board of directors that oversees the management of the corporation on behalf of its owners and ensures legal and regulatory compliance. Boards frequently include senior executives and directors from other organizations. The linking of those individuals' multiple affiliations is referred to as board interlocks. Boards are networks of individuals whose ego networks constitute bridges to the other organizations of which they are members. As a result, multiple organizations are linked by way of the boards on which their members serve.

Interlocking boards can serve four organizing functions: cooptation, access to resources, control, and legitimation. One means of dealing with potentially disruptive elements in the environment is through cooptation. By assimilating external actors into the organization via membership on the board of directors, outside directors may come to share the organization's point of view and may even act on the organization's behalf. Organizations depend on access to resources from their environment, and they move proactively to manage such dependence. Interlocking boards provide the organization with relational assets, such as trust and shared knowledge, and board members may be able to provide direct access to needed resources. Interlocking boards are also a means of corporate control and monitoring. For example, bankers sit on corporate boards in order to protect capital at risk in financially troubled firms. Their presence on the board of directors allows them to be informed about the firm's financial status and actions being contemplated by management, and they may be able to influence or even control company actions that might affect their ability to recover loans. Finally, the composition of the board of directors affects the firm's legitimacy and reputation. Interlocking boards composed of high-status directors help legitimate the firm to potential sources of capital, labor, and other resources.

Multifirm Ties

Firms in a variety of industries have chosen to focus on their core activities and to outsource noncore activities to external providers. As a result, activities that could be performed by a single firm are instead performed by multifirm networks (Miles and Snow, 1986). The main organizing benefits of the multifirm network design are flexibility, the variety of capabilities that can be assembled, and the economies of scale and experience that can be leveraged in each activity. The typical multifirm network organization is also hierarchical, organized around a lead firm that works dynamically with its network providers to produce and deliver products and services (Dyer and Nobeoka, 2000). The design of a multifirm network consists of four key choices: forming the right types of external relationships, which companies to partner with, how to structure the relationship between partners and suppliers, and determining the kinds of supporting policies that are needed (Galbraith, 2014). By networking with external suppliers and partners, a few lead firms can organize an entire industry (Mathews, 2012).

Community

A community is a collective of actors who share common values and interests. As a means of organizing, the community provides a platform for the independent members to collaborate with one another by committing to a set of shared values and norms that exert moral suasion to regulate member behavior. By substituting resource commons, protocols, and infrastructure for hierarchical leadership and control, a community can be largely self-governing (Fjeldstad et al.,

2012). The community form of organizing is prevalent in knowledge-intensive sectors where the knowledge base underlying products and services is complex, growing, and widely diffused, requiring interorganizational collaboration to assure the full utilization of continuously developing knowledge (Powell et al., 1996). The community organizational model offers members the opportunity to collectively develop solutions and capabilities, thereby achieving a collaborative advantage.

Conclusion

Network is a valuable concept in the organization sciences. Among organization theories, network theory has been one of the most useful in advancing our understanding of organizations and their environments. Organizations are networks of formal and informal relationships as well as nodes in the larger societal networks in which they are embedded. As organizations and their environments continue to coevolve, network theory and analysis will be one of the major tools used to study them.

Networking for School Improvement

Steven Katz, Ontario Institute for Studies in Education/University of Toronto, Toronto, ON, Canada

Abstract

Networks of teachers, administrators, schools, and districts have become a pervasive mechanism in education for reaching beyond traditional boundaries. Some networks are formally organized around a common goal, whereas others unite schools into a common organizational structure. Some networks are intentional in their origins and organization, and some are informal, arising in spontaneous ways. Although many positive characteristics are attributed to networks, the question of how networks 'work' has been difficult to answer. This article takes up that question, with an appeal to a research-based theory of action that elucidates how successful networks function as innovative knowledge communities.

Why Networked Learning Communities?

For decades, numerous school improvement models have attempted to reform the thinking and practices of practitioners with the explicit intent of increasing student learning and achievement in schools. Introducing reforms into classrooms and schools has generally accomplished superficial changes to practices that have not easily translated into sustainable improvement for student success (Hargreaves, 2003). In an effort to intentionally create the level of deep learning necessary for practitioners to make meaningful changes in their classrooms, professional networks are increasingly being promoted as mechanisms for knowledge creation and mobilization, that can lever the kinds of changes that make a difference for students.

In a knowledge society, lifelong learning is a cornerstone of the flexibility necessary for highly skilled and educated people to take on novel tasks and continuously adapt to new and changing environments. As we exit the industrial age, characterized by a 'finite' conception of resources, a 'controllable' conception of information, and a 'sequential and task-specific' conception of learning, the notion of networks takes on increased relevance (Allen and Cherrey, 2000). Specifically, networks provide an operational construct for educational provision and a new vehicle for achieving change.

In this knowledge society, practices for facilitating knowledge creation and mobilization are considered to be key tenets of educational provision. Knowledge is the most critical resource for social and economic development (Hakkarainen et al., 2004). Change-directed improvement comes in the form of creating new knowledge or adding value to existing knowledge rather than simply appropriating existing knowledge resources. A fundamental challenge for education then is to organize work with knowledge in a way that facilitates ongoing knowledge building and sharing among members of the community. As Hakkarainen et al. (2004) explain, members of the community need to develop competencies that allow them to function as 'knowledge workers.'

In *Working Laterally*, Hargreaves (2003) describes the demands of knowledge creation (and its supportive competencies) in terms of innovation. Knowledge creation (or transformation) is – in a word – innovation. Innovation, for teachers, is about learning to work differently in order to work better. For teachers, most innovation is the creation of new professional knowledge about their work.

Historically, the route to understanding (and supporting) innovation has been subject to individualistic bias. This bias has paid more attention to mental processes and events at the level of individual agents than to activities that are distributed across several agents in particular contexts and are dependent on characteristics of social organization. Alternatively, many proponents of the knowledge society focus almost exclusively on the organizational level and examine those organizational practices that elicit knowledge creation to the exclusion of cognitive competencies, without which participation in this society is impossible. Hakkarainen et al. (2004) argue that both are necessary. Networks, as a dynamic organizational form that can mediate between the personal and social worlds, have the potential to capture the complex and reciprocal relationship between individual and collective competencies.

How Do Networked Learning Communities 'Work?'

The question of function, or how networks 'work,' has been difficult to answer. At the broadest level, they support diverse goals, like broadening opportunities and sharing resources (Muijs et al., 2010), but the route to school improvement is not always clear. Judith Chapman and David Aspin (2003) suggest the following possible pathways of function:

- Networks offer a means of assisting in the policy implementation process by linking policy both horizontally and vertically.
- Networks provide a process for cultural and attitudinal change, embedding reform in the interactions, actions, and behavior of a range of stakeholders.
- Networks provide for an opportunity for shared and dispersed leadership and responsibility, drawing on resources in the community beyond education.
- Networks can be capacity building insofar as they are able to produce new knowledge and mutual learnings that can then offer feedback and inform public policy.
- Networks can move attention away from a preoccupation with micro-level change at the individual site and function at the meso-level to strengthen interconnections and spread innovation across all levels – micro, meso, and macro.

The educational landscape is populated by networks with a multiplicity of variations. In England, government sponsored networks developed to encourage and support continuous cooperative learning at all levels of the education system. England's Networked Learning Communities (NLC) program was the largest government sponsored school-to-school networking initiative of its kind in the world. In the United States, the growth of organic networks of teachers and administrators has taken place over the past 30 years without a formal government-sponsored infrastructure. Some networks join teachers and/or schools together on a national level. The National Writing Project, for example, is a teachers' national network of writing (Lieberman and Wood, 2002). Other networks are bound by jurisdiction, such as the Consortium for Educational Change, a network of school districts in Illinois, created to improve student achievement by assisting member districts and schools to become collaborative, high-performing organizations. Likewise, the Bay Area School Reform Collaborative (BASRC) is a network of schools in the San Francisco Bay Area that collaborates to achieve equity-minded school reform (Center for Research on the Context of Teaching, 2003).

Understanding networked learning communities is best accomplished from a research-based and empirically-validated theory of action perspective that has to begin with the end in mind (Katz and Earl, 2010). Rather than networking for the sake of networking, the explicit and intended impact of networked learning communities is to enhance student learning and engagement (the ultimate outcome), the antecedent of which is a change in teacher practice (an intermediate outcome). Changed teacher practice, in turn, is preceded by a protocol of knowledge creation and sharing (intermediate outcome). It is here – knowledge creation and sharing – that the collaborative underpinnings of networked learning communities as a dynamic organizational form find expression and effect.

The task of 'enabling' knowledge creation and sharing can be conceptualized as the outgrowth of a community of practice (COP) (Veugelers and O'Hair, 2005) or – to better underscore the key ingredient of intentionality – an innovative knowledge community (IKC) (see Paavola et al., 2004, for a description). That is, while networks differ in the way they go about doing their work, they share the general function of bringing participants to build IKCs. In 'theory of action' terms, networks, as collaborative organizational forms, support particular ways of working that find expression as these IKCs within two distinct organizational units – the network itself and the schools that are represented.

Several studies have found positive associations between the presence of COPs (or IKCs) within particular schools and the schools' success in enhancing student engagement and achievement (Bryk and Schneider, 2002; McLaughlin and Talbert, 2001). Research (Katz and Earl, 2010) suggests that networks can foster the development of school IKCs by: (1) linking newly emerging ones to their more developed counterparts and (2) creating new IKCs at the network level that enable knowledge creation and sharing. What becomes important then is the strength of attachment between schools and networks such that established school-level IKCs can upload their key feature practices into the network – thus creating a network IKC – that in turn allows other school IKCs to download and instantiate these enablers of knowledge creation and sharing.

What connects schools to networks (and networks to schools) are, ultimately, people – whether it be directly through active participation or through the construction of artifacts that serve boundary spanning functions. The study of individuals as the connective tissue of networks takes place at the individual level and is typically accomplished through social network analysis (see Hite et al., 2005, for an example). Social network analysis considers the nature and roles of particular individuals as they connect to others, both within and across organizational boundaries. But beyond such social interactions, a networked learning theory of action needs to consider the organizational (school and network) products (in terms of IKC practices that *enable* knowledge creation and sharing) of these interactions.

What Are the 'Key Enablers' of Successful Networked Learning Communities?

Research (e.g., Katz and Earl, 2010) has identified six key *enablers* of successful networked learning communities, each of which operates within the schools and the network: *purpose and focus*, *relationships*, *collaboration*, *inquiry*, *leadership*, and *capacity building and support*. Each of these constitutes a complete area of inquiry, with an associated research base, on its own. Networked learning communities 'work' because knowledge creation and sharing are enabled by a constellation of practices defined by these enablers. While a fulsome treatment of each is beyond the scope of this article, below is a brief initial orientation to each of the enablers.

Purpose and Focus

Having a fundamental and clear organizational purpose is critical to the success of networked learning communities. A learning focus is likely to have a more direct impact if it is focused in ways that are concrete and useful (Timperley and Robinson, 2003); high leverage in fostering student learning (Marzano et al., 2001); compelling, challenging, and shared (Lieberman and Grolnick, 1996; Bryk et al., 1999); and appropriate to the context (Marzano et al., 2001). A compelling and high leverage learning focus is based on evidence that it can have significant impact on teaching practices and student learning. A challenging focus is one that requires teachers to reconceptualize, unlearn, or make changes to existing practice and structures, legitimating the change process by making the status quo more difficult to protect, and offering opportunities for joint attention to issues that are larger than any one school could address alone (Timperley, 2004). Finally, the learning focus should be 'right' for the participating schools, given their particular context, history, and needs.

Relationships

Relationships are the 'connective tissue' of networked learning communities (Allen and Cherrey, 2000) and provide the social capital that allows people to work together over time and exceed what any of them could accomplish alone

(West-Burnham and Otero, 2004). Relationships create a common language and a sense of shared responsibility, provide channels for communicating and disseminating information to one another about network members' expertise, and develop readiness to trust one another (West-Burnham and Otero, 2004; Veugelers and O'Hair, 2005).

Trust is a key condition of productive relationships. Indeed, Bryk et al. (1999) found that social trust among members of a group was the strongest facilitator of professional community. They propose that a base level of such trust may be necessary for a professional community to emerge, but working and reflecting together can also build trust and strengthen relationships. In relationships, conflict is inevitable – and indeed valuable – but robust and trusting relationships among network members can allow them to work together even when they have different orientations and views (Lieberman and Grolnick, 1996).

Collaboration

Collaboration encompasses much more than relationships. It is intensive interaction that engages educators in opening up their beliefs and practices to investigation and challenge. When colleagues engage in a dynamic process of interpretation and evaluation of practice, they enhance their own practice and that of the profession. This kind of collaboration allows people to address tough problems of teaching (Firestone and Pennell, 1997), build commitment through group understanding (Lieberman and Grolnick, 1996), solve issues of mutual concern (Wohlstetter and Smith, 2000), and spread innovations beyond individuals and single sites (Smith and Wohlstetter, 2001).

Collaboration can be a powerful mechanism for changing ideas and practices, particularly when it involves joint work that includes a balance of personal support with critical inquiry about present practice and future direction (Borko, 2004) and sustained scrutiny of practice, but is not always easy. In fact, moderate conflict is essential for the development of high joint benefit, and the desire to avoid conflicts can undermine this outcome (Engestrom, 1999).

Inquiry

Systematic analysis and professional reflection are regarded as core activities for both individual and collective construction of meaning, and are hallmarks of an 'inquiry habit of mind' (Earl and Katz, 2006). Knowledge creation, especially when people are involved in changing their practice, requires that individuals consider explicit knowledge and share, question, and possibly adapt their tacit knowledge, in order to create new collective explicit knowledge. Little (2005) references a large body of research suggesting that conditions for improving learning and teaching are strengthened when teachers collectively question ineffective teaching routines, examine new conceptions of teaching and learning, find generative means to acknowledge and respond to difference and conflict, and engage actively in supporting one another's professional growth. The inquiry processes of questioning, reflecting, seeking alternatives, and weighing consequences promote the 'transparency' of what otherwise might remain unobservable facets of practice, making tacit knowledge visible and open to scrutiny.

Collaborative inquiry creates an opportunity for educators to work together searching for and considering various sources of knowledge (both explicit and tacit) in order to investigate practices and ideas through a number of lenses, to put forward hypotheses, to challenge beliefs, and to pose more questions. When educators have an inquiry habit of mind, they have developed a way of thinking that is a dynamic iterative system for organizing ideas, seeking out information, and moving closer and closer to understanding some phenomenon together.

Leadership

Networked learning communities include many levels of leadership – both formal and informal. Networks need some system of leadership to direct the work of the network itself, which usually coexists alongside the formal leadership of administrators in schools. Although the leadership literature continues to emphasize the role of principals in successful change and instructional improvement, leadership models are increasingly focusing on what Rowan (1990) called 'network' patterns of control, where leadership activities are distributed across multiple people (Heller and Firestone, 1995). Formal leaders (e.g., principals) provide leadership by encouraging and motivating others, setting and monitoring the agenda, sharing leadership, providing support, and building capacity. At the same time, networked learning communities encourage distributed leadership in schools and across the network, with many people with and without formal positions of authority providing a range of leadership functions such as leading particular initiatives, participating in collaborative groups, supporting colleagues learning, and sharing their knowledge with others.

Building Capacity and Support

Harris (2001) defines capacity building as being concerned with creating the conditions, opportunities, and experiences for collaboration and mutual learning. Years of school improvement research have shown that improving schools are ones that take charge of change, rather than being controlled by it (Stoll and Fink, 1996). As Senge (1990) describes it, a learning organization is one that is continually expanding its capacity to create its future. In networked learning communities the focus is on creating the conditions to support individual and collective learning through all of the processes described in the previous key enablers. Building capacity depends on intentionally fostering and developing the opportunities for members to examine their existing beliefs and challenge what they do against new ideas, new knowledge, new skills, and even new dispositions. When networks are focused on learning, they intentionally seek out and/or create activities, people, and opportunities to push them beyond the status quo within their school and network developments.

Putting It All Together

In summary, networked learning communities represent complex interactions between structures and activities that are

intentionally dedicated to creating new knowledge and sharing it broadly. A number of features have been shown to create the conditions that foster knowledge creation. When educators participate in focused relationships for collaborative inquiry, they open themselves to new ideas and to challenging their views through interaction with others and with formal knowledge. Leaders, both formal and distributed across roles, can provide vision, accountability, and capacity building opportunities for engagement in the activities that move professional learning and knowledge creation forward.

Networks and Cultural Consumption

Mark C Pachucki, Harvard Medical School, Boston, MA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Scholars of culture have been increasingly concerned with the roles played by interpersonal social networks in relational cultural processes. This article highlights the ways that social network composition and dynamics can shape individuals' cultural consumption choices and the ways that consumption can shape the structure of individuals' social networks. Attention is given to symbolic aspects of cultural consumption as well as practical aspects of consumption. While much of the research on this topic emerges from the sociology of culture, a broader focus illustrates productive links with health-based and cognitive perspectives.

Definition and Intellectual Context

Scholars of culture have been increasingly concerned with the roles played by interpersonal social networks in relational cultural processes (for recent reviews, see Mische, 2011; Pachucki and Breiger, 2010). In this article, the term 'social networks' refers to the web of human associations and interactions that constitute an individual's social group (Breiger, 2009; Scott, 2000). The term 'consumption' largely refers to cultural consumption – the ways that individuals broadly enact their cultural tastes and leisure-time activities (i.e., fashion, music, art, television and film-viewing, reading, religious attendance, political engagement, and sporting activities) (Bourdieu, 1984). However, consumption can also refer to physiological ingestion (i.e., food and other substances) as a type of cultural consumption.

This article highlights the ways that social network composition and dynamics can shape individuals' cultural consumption choices, and to a lesser degree it also documents the idea that consumption choices can shape the structure of individuals' social networks. A brief discussion of the history of this topic is followed by a review of current theory and research, concluding with an identification of challenges and future directions. Because of space limitations, this article is illustrative of key works rather than exhaustive of the corpus of growing literature. Most attention is accorded to research that empirically measures some aspect of social network structure and attempts to discern the relationship between social ties between individuals and these same individuals' cultural consumption practices.

Though research in this area is centered primarily around topics of musical taste and arts participation in the sociology of culture, there have been other emergent clusters including the ingestion of food and drink as a form of cultural consumption that affects health; different forms of cultural consumption involving online and offline social media; and consumption of knowledge and the academic sphere. By bringing these conceptually related but often separate intellectual contexts into dialogue with one another, we might identify productive areas for investigation in this growing subfield.

History

The idea that cultural consumption is shaped by forms of socialization has early roots in the work of Thorsten Veblen (2007[1899]), whose well-known work on lifestyle habits generated the phrase 'conspicuous consumption' to refer to the practice of signaling social status through one's consumption choices. Yet more formal discussion of cultural consumption and social network interaction would not follow for some time. It could be argued that some of the earliest sociologists to focus informally on networks in the context of cultural consumption were Harrison White and Cynthia White (1965) in their research on the contexts of artistic creation in French salon society, as well as Howard Becker's (1982) classic treatise on art worlds. Neither text employs formal measurement of social networks. However, the authors' discussions of how artist socialization shapes artwork and audiences clearly evince a sympathetic understanding of how network processes shape cultural consumption, and vice versa.

The oeuvres of both Pierre Bourdieu and Richard Peterson have been highly influential in sociologists' understanding of how cultural consumption is shaped by social status position. Bourdieu (1984) extensively investigated cultural consumption and lifestyle, and his ideas of 'field' could be considered a distant relative of the idea of 'social network' in that he envisioned a highly connected, mutually reinforcing 'field of action' where human and institutional actors and their dynamic relational circumstances constantly re-molded the contours of a domain of activity (Bourdieu, 1993). Peterson and colleagues' explorations of how high-status individuals differentiate themselves through their breadth of consumption – the concept of 'omnivorousness' – offers an alternative mechanism of cultural reproduction (e.g., Peterson and Kern, 1996; Peterson and Simkus, 1992). Like the earlier relational tendencies of White & White and Becker, neither Peterson nor Bourdieu operationalize the idea of social networks beyond their theoretical frames. Regardless, the tension between Bourdieu's and Peterson's visions of how cultural inequality is reproduced has been fruitful for paving the way for scholars to investigate possible roles for network mechanisms. For example, Lizardo (2013) finds that individuals who engage in

a broad palette of cultural participation are more likely to make use of their network contacts to find a job.

Current Theory and Research

Social Networks, Cultural Participation, and Tastes

Investigating possible links between network diversity (or heterogeneity) and symbolic cultural consumption has been a fruitful line of inquiry for scholars. One of the earliest studies to empirically analyze network affiliation and cultural consumption in a rigorous fashion is Erickson's (1996) study of genre knowledge of security workers in Toronto. To assess genre knowledge, Erickson probed sports, art, books, restaurant, and magazine consumption; for network variety, the author asked respondents if they knew someone working in 19 occupation categories, and whether that person was kin or a friend. Greater network diversity – defined as having contact with people in different occupation class locations – was linked with greater variety in forms of cultural consumption. In a similar vein, Relish (1997) studies music genre preferences using the 1993 US General Social Survey (GSS). He measures network complexity by counting the number of associations to which a respondent belongs, geographic mobility since youth, and community type. He finds that a strong association between education and breadth of genre preference is diminished with the introduction of network information, suggesting that networks play a significant role in the development of musical preferences.

In their research on general cultural participation, Warde and Tampubolon (2002) describe trends in association membership and frequency of leisure-time activities using two waves of the British Household Panel Survey spanning 1997–99. Using association membership as a proxy for social capital, they report on cross-tabulations and find group membership to be associated with greater frequency of leisure-time activities. The authors also construct a measure of social distance between best friends using similarity in sex, age, and location and observe that having a highly similar best friend increases the likelihood of recreational activity of various types. By enumerating personal networks of university students, Kane (2004) discovers a gendered dimension to cultural participation in a range of activities. In contrast to earlier studies, Kane's questions to respondents were designed to elicit information about specific network alters, following a more sophisticated network design. By calculating respondents' network density and heterogeneity measures of race, religion, and gender in one's set of reported alters, she reveals that network density is positively associated with attending sports events and negatively associated with museum and gallery attendance. Greater network heterogeneity increased the likelihood of high culture participation, and network effects were greater for women than men. In contrast to the prior research that seeks to understand how networks shape cultural consumption, Lizardo (2006) employs indicators of cultural participation to explore the opposite possibility: that cultural tastes also shape network structure. Using the 2002 module of the GSS, he examines personal network size and tie strength to show that highbrow forms of consumption lead to larger networks of strong ties, while popular consumption leads to larger networks of weak ties.

The analysis of music tastes as a proxy for consumption habits has been productive for many network scholars. Like Relish (1997), Schultz and Breiger (2010) use the 1993 GSS to examine musical genres liked by respondents. However, their starting point is the idea that theories involving the strength of social ties, and sociability more generally, should take into account cultural objects and relations. The authors posit that strong ties emerge from 'weak culture' – from venues of small talk, from tentative efforts to engage common ground with others, and from the efforts required to maintain a relationship. They find that the more music genres a respondent 'likes rather than loves' (their measure of weak culture), the less likely are they to perceive Americans as generally fragmented in their values, compared with those respondents who like fewer genres. In an innovative examination of how network social influence shapes musical tastes, Salganik et al. (2006) developed an online experiment in which participants downloaded and rated music while in some cases aware of others' online expressed preferences. The authors find that knowledge of others' preferences increased inequality in song ratings: knowledge of others' preferences translated into popular songs becoming more popular while unpopular songs would be even more unpopular. Finally, Crossley (2009) merges historical accounts of the Manchester punk music scene between 1976 and 1980 with network mapping techniques to trace connections between key social actors, among them musicians, industry figures, record labels, and fan clubs. Using qualitative historical data to give depth to purely structural accounts of network dynamics, Crossley identifies shared interests, the propensity for redundant information among those with strong ties, and the diffusion of reputation as relevant mechanisms.

Longitudinal research on networks and cultural consumption has been rare due to intense data and analytic demands, though this is quickly changing. A promising line of research involves a class of actor-oriented statistical models that seek to discern mechanisms responsible for observed network structures and consumption patterns using simulation techniques. One example is the adolescent preference research of Steglich et al. (2006), who use data on friendship ties, substance use, and music genre preferences collected from a cohort of Scottish secondary school students. They find that certain types of consumption behaviors shape friendship patterns. More specifically, listening to rock music increases one's popularity in the network, classical music listeners tend to affiliate with one another, and those who drink alcohol cluster together in the network. In a study of the preferences of college Facebook users at an American university, Lewis et al. (2012) examine the relationship between Facebook friendships and music, movie, and literature consumption preferences. In contrast to prior research that examines genre preferences in culture consumption, the authors were able to analyze respondent similarity in the much more precise level of performer preferences (in the case of music), specific movie titles (in the case of film), and specific authors (in the case of literature). They model network and behavioral coevolution using an actor-based approach in order to separate social selection and network influence. For music taste selection effects, they find that 'lite/classic rock' and 'classical/jazz' fans form and maintain friendships with one another more than their peers. For film selection effects, they

observe that 'dark satire' and 'raunchy comedy/gore' viewers are more likely to be friends. Yet of all the possible consumption behaviors, only classical/jazz listeners are likely to influence others to adopt that taste. An overview of the authors' broader study design, scope, and data-gathering approach is described elsewhere (Lewis et al., 2008).

Social Networks, Media Usage, and Knowledge Consumption

Comparative studies of different types of media usage are key themes for a range of scholars across different national contexts. Cardon and Granjon (2005) examine personal networks of middle-class students in France, motivated by the paradox that while studies of cultural practices often involve measurement of collective activities, these same studies rarely explore relational context, instead treating actors as autonomous individuals. They begin with ego-network enumeration of a small sample of young men and women, followed by interrogation of their media consumption as well as whom they engage in these activities with. Their descriptive network analysis – and importantly, reports of discussions of the resulting sociograms with the original respondents – gives a rich sense of different types of cultural consumers. They find three general types of young adult media users: those who engage in cultural activities and keep their groups of alters separate, those who engage with different sets of alters and spread their tastes across these various groups, and those who maintain a core network based on cultural activities and who draw other alters into that core. In contrast, Kraaykamp et al. (2007) focus on the dyad as a precursor to network processes and examine how a person's social status and their significant other's social status affect media consumption – specifically, book reading and television watching. Relying upon multivariate analysis of a large longitudinal survey of Dutch adults, they discover a significant relationship between the partner's status and ego's media consumption. Those with partners of higher status tend to consume more literature, while those with partners of lower status consume more television.

A growing number of scholars are also beginning to investigate the roles that the Internet plays in our cultural consumption habits. Kayahara and Wellman (2007) conducted a study of information search behavior in order to compare the online and offline ways in which individuals learn about cultural activities. Using in–home interview data from Toronto residents, the authors find that interpersonal relationships are the primary source for learning about activities but that the Internet functions to enhance and confirm their understandings. Information search across different modes of interaction is also a concern for Tepper and Hargittai (2009), who study methods of discovery about new music by college students. Through fielding surveys to students at three different universities, they compare the relative efficacy of interpersonal social networks, mainstream media, and digital media in informing new music consumption. The authors find that music listeners with omnivorous tastes are nearly four times more likely to learn about new music from people in their social network as opposed to the other pathways, and that Internet methods of discovery tend not to be disproportionately influential in shaping music discovery.

Another emerging area of research concerns the university as a site for cultural consumption. Research in this area investigates the ways that academic socialization processes shape students' experiences. For example, Kane (2011) seeks to understand how the transition from high school to college affects students' personal network composition. Using a combination of surveys and interviews of incoming students at an elite university at arrival and 1 year later, she examines the density of personal networks, as well as various types of network heterogeneity (ethnic, gender, regional, and religious). Over time, Kane finds network density decreased and network heterogeneity of all types increased. For the young men in her sample, group-based affiliations (such as sports teams) formed the primary basis for social tie development, while women were more likely to spend time cultivating relationships outside a formal group structure. Diversity is also a central interest of Benediktsson (2012), who uses the National Longitudinal Study of Freshmen to study how cultural consumption is related to the racial heterogeneity of incoming college students' social networks at 27 universities. Through the analysis of prior and current arts, religious, political, and sports participation, he finds that cross-racial contact appears to vary by the type of cultural activity. More specifically, religious group participation is associated with higher levels of racial homophily than the other cultural activities, though students are more likely to encounter students of different races (heterophily) through affiliating with arts groups. In a very different type of investigation concerning both the consumption and production of knowledge in academia, Rawlings and Bourgeois (2004) use the network concept of structural equivalence to measure how categories of specialization emerged in the field of agriculture. By combining a historical approach to tracing the development of academic credentialing processes with network tools, they show how symbolic boundary processes and organizational dynamics shaped agriculture as an academic field.

Social Networks and Physiological Consumption (Ingestion)

A much more literal definition of consumption that has rarely been integrated with discussions of symbolic forms of cultural consumption is the voluminous health literature on food consumption and substance use. Here, reported ingestion of certain food items or beverages and miscellaneous drug-related behaviors are often analyzed as risky behaviors associated with poor health status. Scholars researching these topics are beginning to productively identify how certain of these forms of consumption are patterned in social networks.

Alcohol consumption has been a recurrent theme of investigation for network scholars. Among the earliest pieces on this topic is a demographic study of Norwegians' drinking during the nineteenth and twentieth centuries. Skog (1986) tests a hypothesis that long waves of cyclical alcohol consumption may be recurrent throughout history using time-series analyses of trends. Finding some evidence of this cyclical pattern in the time period evaluated, he formally models network interactions to evaluate how microlevel interactions shape chains of indirect influence and changes in drinking culture. In a study of the social contexts of adults' risky health behaviors, Latkin et al. (1996) examined the influence of peers'

alcohol consumption on egos' drug-related risky behaviors (injectable cocaine, injectable heroin, crack cocaine, alcohol, having multiple sexual partners, and having casual sexual partners). Peer alcohol consumption was observed to be associated with egos' drinking behaviors, as well as egos' sexual behaviors.

In a large-scale alcohol consumption study using the National Longitudinal Study of Adolescent Health (Add Health), Gaughan (2006) argues that gender effects are not well understood in peer influence models of adolescent health behavior. The author examines social influence in alcohol consumption of seventh to twelfth graders between two waves of the study, evaluating several types of possible influence – general 'friend to friend' influence, and more specific 'female to female,' 'male to male,' 'female to male,' and 'male to female' directions. While Gaughan finds mutual influence among same-sex friends, in mixed-gender friendship there is evidence of only boy to girl influence, not the reverse. In another notable study based on the Add Health cohort, Kreager and Haynie (2011) specify actor–partner interdependence models in a longitudinal setting to help disentangle selection from influence. While the authors primarily focus on the effect of romantic partners' drinking on an ego's drinking, they also consider the role played by ego's friends, and that of the friends of romantic partners as well. Their findings suggest that partners' drinking is associated with ego's future binge drinking, and that the drinking behaviors of the friend group of a partner is independently associated with ego drinking. While couples tend to become similar in their drinking behaviors over time, there is little evidence of assortative mating with respect to drinking among adolescents. In a large network study of alcohol consumption among adults, Rosenquist et al. (2010) explore how alcohol consumption spreads through relationships over time in a social network. Using data from the Framingham Heart Study, a well-known prospective cohort study designed to study cardiovascular risk, the researchers discover evidence of spread that extended to three degrees of separation from ego. Additionally, they find that female alters are more likely than male alters to influence alcohol consumption, and that while being surrounded by heavy drinkers increases an ego's likelihood of being a heavy drinker, being tied to abstainers also increases an ego's likelihood of abstaining.

Research on food consumption and networks across the social sciences illustrates how eating is patterned among socially connected individuals. Psychological research on dyadic similarity in eating preferences has shed important light on networks considered as chains of dyadic interactions. In one example, Rozin et al. (2004) examined dyadic similarity in food preferences among peers in two different age groups – elementary school children and freshman college roommates – in order to assess the likelihood of peer influence. In order to discount the role of shared culture, the authors compare food preferences of actual pairs of friends with randomly assigned friends. Across both age tiers, the authors find little evidence of mutual influence beyond what would be expected in same-gender randomly assigned peers. In a longitudinal study of several thousand adults from the Framingham Heart Study, Pachucki et al. (2011) examined similarity in self-reported food consumption among peers of different relationship types – spouses, siblings, and friends – while controlling for network position in the greater social network. The authors find seven different eating patterns in the population, and substantial concordance in spouse eating patterns, some concordance in sibling eating patterns, and little concordance in friend eating. By specifying lagged regression models in which the relationship between an alter's prior food consumption and ego's current consumption is assessed, the results provide evidence of a social influence process. Finally, in a recent study of several thousand Minneapolis adolescents across multiple schools, Bruening et al. (2012) calculated measures of healthy eating behaviors in one's peer group (i.e., ego network). Specifically, the investigators examined the separate contributions of ego's friend group and best friends' behaviors on the frequency of breakfast, servings per day of fruit, vegetables, whole grains, and dairy foods. While the propensity to eat breakfast and consume whole grains and dairy were each significantly associated within friend groups and best friend pairs, there was less evidence that adolescents share similarities in levels of fruit and vegetable consumption. In terms of unhealthy foods, a rigorous sociocentric investigation using a stochastic actor-based framework reveals that adolescent intake of low-nutrient, energy-dense foods is predicted by the intake of socially connected friends (De la Haye et al., 2013).

Cigarette smoking as a consumption practice has also been the topic of a great deal of social network research. In one of the first studies to link smoking with peer group structure, Ennett and Bauman (1993) studied the smoking habits of a cross-sectional panel of ninth graders in North Carolina. By analyzing clique membership, liaison positions, and social isolates, they find that smoking is most strongly linked with social isolation. In a longitudinal study, Alexander et al. (2001) examined two waves of the Add Health study to examine the role of peer influence on smoking behavior among seventh to twelfth graders. Through measurement of peer smoking exposure, the authors discovered that students with a peer network in which more than half of one's alters smoked tobacco were almost twice as likely to be current smokers. The ego was also twice as likely to be a current smoker if ego's best friend had been a smoker. Additionally, ego popularity contributed to a small but notable risk of being a current smoker. Valente et al. (2005) seek to extend this last finding concerning popularity, and ask if popularity predicts subsequent smoking initiation among middle-school students at several schools. For the students in the study, popularity was strongly predictive of increased susceptibility to start smoking and also having ever smoked; the authors also found that different measures of network centrality were associated with smoking initiation.

More methodologically sophisticated treatments of peer influence and smoking over time involve the analysis of multiple panels of adult data in an observational setting (Christakis and Fowler, 2008) and actor-based modeling approaches of adolescents (Mercken et al., 2009). In a study of more than 30 years of smoking behavior among more than 12 000 Framingham adult cohort members, Christakis and Fowler discover that while smoking behavior clusters among interconnected actors in the study, entire subgroups tend to quit at nearly the same time, and the relative centrality of smokers in the network declines over time. In contrast, Mercken and collaborators employ a series of stochastic actor-based models in order to distinguish the roles of peer selection

from influence in the smoking behavior of adolescents across multiple high schools in six European countries during more than 2 years. The authors found strong evidence for selection in all six countries, but evidence for influence in only two.

Challenges and Future Directions

Studies of consumption that span topical domains have potential to inform more incisive theory by extending their scope beyond a narrow focus on only one type of consumption. For instance, in an unusual population-based health study, Bygren et al. (1996) examined links between Swedish lifestyle habits and health while controlling for the presence of a strong social network. They discovered that greater cultural consumption in performing arts attendance, reading, and making music is associated with reduced risk of mortality. Though by today's standards a very rough social network indicator was used (a binary measure indicating frequent versus sparse friend group contact), the researchers found that among men the presence of one's social network elevated one's mortality risk, while among women the absence of a social network elevated risk. Another example illustrates how the conceptual distinction between cultural consumption and production can be illusory (Giuffre, 2001). To wit, while art critics function as bridges between artists and the consuming public and are thus neither producers nor consumers of art, it can be reasonably argued that as a group of highly interested cultural consumers equipped with professional expertise, art critics constitute a peculiar audience class unto themselves. This nuance is pertinent to a study of fine art photographers and reviews of their gallery exhibitions in which network ties between artists and galleries classify structurally equivalent groups of relationships (Giuffre, 2001). In examining the links between these artist–gallery groups and the artists' critical reviews, Giuffre discovers that the type of artist discerned through analysis of artist–gallery relations corresponds to the frequency and content of reviews by critics. Research such as these two examples enriches our knowledge by illustrating the links between consumption across ostensibly separate life domains, as well as the shrinking distance between producer and consumer in modern life.

One of the challenges for consumption research is to integrate how we theorize the intersection of the symbolic and pragmatic aspects of cultural consumption. Research on arts participation, for instance, has largely concerned itself with how taste preferences (a symbolic dimension) shape or reflect participation, and issues surrounding access to and constraints on participation (a more pragmatic dimension) have been more peripheral. Networks can affect the development of taste as well as enhance or constrain access. Certainly in research on food consumption, issues of taste have been more interesting for sociologists of culture, while practical issues surrounding food as nutritive fuel have been the domain of health research. A closer integration stands to help us better theorize how biological processes are related with social processes. Growth in this area will benefit from an interdisciplinary focus on cognition and decision-making processes, areas of scholarship that have traditionally been the purview of social psychology.

Another key challenge for future scholars in this field is to integrate study of online and offline cultural consumption and social networks. With several exceptions, this article has largely been concerned with understanding social networks as built from face-to-face human relationships, even though online social media are beginning to transform the very notion of how we understand a social network. Questions surrounding how online social networks shape cultural consumption are increasingly of interest to scholars and change how we think about the nature of relationships. In a contemporary society where individuals have multiple and overlapping online and offline identities, this is not a trivial concern.

Networks and Meaning

Abstract

Social networks are intricately interwoven with forms of meaning like roles categories, identities, and relationship frames. This article offers a comprehensive overview of the recent strand in sociological network research (around Harrison White) that studies this interlinkage, and of its most important theoretical arguments. Social networks are conceptualized as patterns of interaction that are governed by an underlying structure of expectations. The meaning of networks comprises the identities of the actors in the network, the relationships at play, the categories, roles, and institutions structuring the network symbolically, and the styles that develop in a network.

Introduction

The traditional approach in social network analysis is to study the structure (pattern/regularities) of relations. Relationships in these early studies were typically measured in binary terms as existing or not. The meanings of ties, on the other hand, were intentionally ignored or bracketed. While proving fruitful in a number of important studies, this approach displays particular limits because it reduces social phenomena to a-cultural structures. As a response to these limits, recent developments in North American network research around Harrison White have taken a 'cultural turn.' Juxtaposed against a traditional focus on structure, authors like White, Ronald Breiger, Ann Mische, Mustafa Emirbayer, John Mohr, and Paul McLean contend that meaning ought to be treated as important in social network analysis. More specifically, the structure of networks is seen not only as a conduit for the distribution (or bottlenecking) of cultural forms, but as itself based on forms of meaning. This includes the construction of identities of actors involved in interaction, the stories that make and are made in networks, the patterning of ties by institutions, roles, and categories, the imprint of relationships with frames like 'love,' 'friendship,' and 'enmity,' and the emergence of various styles in networks. This article provides a systematic overview of these arguments. It first offers a brief overview of the concept of meaning, delineating it against the parallel concept of culture (1). The most important approaches linking social networks with a concern for meaning are sketched next (2). The last section discusses the core concepts of identities, stories, roles, categories, relationship frames, and styles with regard to their role in networks (3).

Conceptualizing Meaning

Over the last 100 years, meaning has continuously remained one of the core concepts in sociology. How exactly meaning has to be conceptualized, however, differs dramatically in the most important approaches, from Max Weber's theory of action and symbolic interactionism, to Pierre Bourdieu's theory of practice, neo-institutionalism, and Niklas Luhmann's systems theory. Weber treats meaning as *subjective* and places it in the heads of actors. In this tradition, social phenomena have to be traced to individual action, with individuals acting on the basis of subjective meaning. Social structures (from ethnic groups to state bureaucracies) are treated as 'social relations' resulting from and consisting in the mutual attunement of subjective meaning that leads to regularities in social behavior. Talcott Parsons paradigmatically traces this attunement to an alter-ego situation where both actors develop expectations on the basis of each others' actions. Following this tradition, social relationships and networks would have to be grounded in subjective dispositions. They consist of the expectations that actors have of other actors' actions; and all action leads to the stabilization or the modification of these relational expectations.

Symbolic interactionism underscores the *intersubjective nature* of meaning, postulating that meaning emerges out of interaction. Close-knit groups of primary relations develop common 'definitions of the situation' that differ from those in other groups. Such definitions of the situation include the sharp distinction from other groups, but also the adoption and playful variation of roles. While symbolic interactionism mostly focuses on group cultures, Gary Alan Fine and Sherryl Kleinman propose a combination with network analysis, arguing that both are compatible in that the negotiation of the meaning of relationships in networks follows the basic interactionist model (1983).

In stark contrast with the action theoretical tradition, Luhmann conceptualizes meaning as mainly *communicated*. While meaning is also thought in psychic systems, sociologically relevant meaning is processed supraindividually in social systems like encounters, organizations, and functional subsystems (economy, law, politics, etc.). In this perspective, social relationships and networks would result from the self-referential operating of communication, with the subjective meaning of actors remaining fundamentally unknown to others (including social scientists). Again they would consist of expectations. But here the term 'expectations' stands for the meaningful channeling of subsequent communication by communicative events.

Bourdieu's theory of practice to a certain degree proposes a middle ground between action and communication. Here, meaning is enacted in *social practices*, guided by the habitus

acquired in interaction in social fields. Practices differ by position in different types of capital and mostly lead to the reproduction of existing structures. Thus social networks, as a form of capital, would yield habitus and practices according to network position, and thus remain relatively stable.

All of these approaches have implicitly or explicitly informed thinking about networks as structures of meaning. It is neither necessary nor suitable to side with one particular approach here. But the concept of meaning has to be demarcated from that of culture, which is closely related and treated in another article (*see* Culture and Networks). Culture broadly refers to forms of meaning (values, symbols, understandings) shared in a social context (country, city, social group, organization). This article focuses on forms of meaning that are commonly and consensually understood, but that are not shared – they affect actors in networks differently. Roles, categories, identities, stories, and styles are likely to be similarly interpreted by the people connected in a network; but those people do not necessarily belong to the very same categories (e.g., gender) – they occupy different roles, feature distinctively in stories, and do not share the same individual identities. These differentiated forms of meaning are instrumental in relating actors to each other.

Meaning in Social Network Analysis

In a sense, social network analysis has always struggled with meaning. The classical structuralism of network modeling and the social capital tradition deliberately bracket the self-understandings of involved actors and the meanings attached to and negotiated in social relationships. Culture and meaning are treated as passive results of network organization, if at all. On the fringes of this emerging network analytical mainstream, various approaches from social anthropology to relational sociology have incorporated meaning (in the various senses sketched above) into their theoretical formulations and empirical studies. This section presents a short overview of their accounts of meaning in networks.

British social anthropology around J.A. Barnes, Elizabeth Bott, and J. Clyde Mitchell invented and elaborated the network concept in the 1950s and 1960s to get away from a one-sided emphasis on meaning in cultural anthropology. In these early studies, self-perceptions and descriptions of social structures by the participants were seen as defective and misleading. Therefore, these perceptions were questioned and superseded by structural analysis: the focus on the 'concrete' relations between actors. While lay descriptions of social structures typically focus on clear-cut divisions between groups and classes, social structure is 'really' to be found in the complex mesh of social relations – the network. However, to bridge the divide between social and cultural anthropology, Mitchell called for the systematic incorporation of a concern with meaning into social anthropology (1969: pp. 20ff.). According to Mitchell, the structural analysis of networks should be complemented with investigation into actors' understandings of social relationships and into the norms governing interaction. These calls have been taken up recently by anthropologists like Russell Bernard, Ulf Hannerz, and Thomas Schweizer.

Mainstream social network analysis had, until recently, followed the path of early social anthropology and largely ignored meaning. Social structures were reduced to patterns of relations without regard to their meaning for participants. Of particular interest are the SNA technique of *blockmodeling* and its treatment of *positions in networks*. Blockmodeling was developed in the 1970s. It analyzes networks by partitioning them into groups of actors with similar relations to other groups of actors. These groups are called blocks or positions. The blocks may consist of actors not connected to each other, but related to other blocks in similar ways. Actors occupying a given position are termed 'structurally equivalent,' and they are seen as playing the same role (elite/clients, etc.) in the network (White et al., 1976).

This technique of partitioning actors into positions followed in the footsteps of Siegfried Nadel, who postulated roles to comprise both cultural and relational aspects (1957). But blockmodeling followed only one side of this lead by emphasizing relational patterns. Methodologically, blockmodeling provides the prime example of the anticategorical imperative because meaning in the network is inferred from the structure of relations rather than posited to exist independently of the network.

Important impulses with regard to the question of meaning come from *neo-institutionalism*. Notably the works of Paul DiMaggio as well as John Mohr feature networks as a core concept and build on the concepts and implications of blockmodeling (DiMaggio, 1986; Mohr and Friedland, 2008). These systematic patternings mirror institutions – sets of rules for the behavior of actors (in their roles) toward each other, encapsulated in 'practical action.' The concrete roles that actors occupy in a network are governed by institutions. These emerge isomorphically in fields. Network analysis, in particular blockmodeling, thus constitutes a suitable technique for the study of the cultural rules in a field.

The development of blockmodeling, the Anglo-American reception of Bourdieu, and neo-institutionalism paved the way for *relational sociology*, sometimes also called the New York school of relational sociology (Mische, 2011). Harrison White's 1992 book *Identity and Control* (a second, thoroughly reformulated edition was published in 2008) marks the programmatic and theoretical core of this endeavor. The most important theoretical argument of the book for our purpose is that *networks are structures of meaning* ('phenomenological realities'). More precisely, networks are seen as social structures linking identities through stories. The identities themselves are not essential building blocks, but result from their relational construction in stories. Thus language becomes an important factor for the construction of networks.

These basic arguments have been taken up and expanded by a number of scholars around White, notably by Charles Tilly, John Padgett, Ann Mische, Mustafa Emirbayer, Stephan Fuchs, David Gibson, Paul McLean, and John Mohr. Relational sociology benefits from a close connection between theoretical elaboration and empirical studies. Its particular conjectures about the connection between networks and meaning are discussed in the next section. Another approach linking networks

with meaning is actor–network theory around Bruno Latour, Michel Callon, and John Law. This approach remains mostly separate from the advances in relational sociology and is discussed in another article (*see* Culture and Actor Network Theory).

Forms of Meaning in Social Networks

This section discusses various forms of meaning with regard to their embeddedness in and their impact on the creation and maintenance of social networks. It draws on the various theoretical treatises and empirical studies of relational sociology without discussing them in detail. The aim is to present a coherent overview of the role of identities, stories, categories, relational frames, and styles in networks and of the rooting of both these forms of meaning and of the corresponding network structure in the process of interaction.

1. Following Harrison White, the relational definition and negotiation of the identities of the involved actors lies at the heart of social networks (2008: pp. 2ff., 9ff.). His definition of *identities*, however, differs from everyday notions of selfhood or group memberships. All interaction involves uncertainties of differing degrees. Identities emerge out of this soup of contingency as actors try to cope with uncertainties. Identities are the 'footings' or points of view that guide action in uncertain situations. Both the bearer of an identity and others react to this footing, thus leading to the formation of ties between individuals. These constructed identities, not preexisting individuals, are related meaningfully in networks.

For example, a group of persons find themselves in close physical proximity at a party and a discussion starts. Initially, the uncertainty is high because the topic of conversation is undecided after introductions have been made. One person could react to the uncomfortable situation by raising the topic of, say, local vegetarian restaurants, thus adopting the identity of conversation-starter. Other individuals now act on the basis of this new information. Someone else may offer a critical view of a new 'farm to table' restaurant in the neighborhood (adopting the identity of local food 'critic'). There is more talk about local restaurants and some people exchange telephone numbers leading to the creation of new ties. Some of those ties may amount to nothing more than telephone entries. But some others may evolve into lasting friendships.

Note that evolving situations lead to changes in identities. For example, two people who go out to dinner now adopt, say, date identities to deal with different types of contingencies that arise in that situation. Identities are thus dynamic constructs that structure and are structured in the course of interaction.

This relationship between identity and networks has been demonstrated in empirical research. In Randall Collins's study of networks in philosophy, the construction of particular authors as important or peripheral to the development of a field is shaped by her position in networks of intellectual influence (1998). But this identity construction in turn makes for a rearrangement of ties, for example, when an author becomes the proponent of a new school of thought gathering around her or when an important author becomes viewed as even more important through a process of preferential attachment.

The continuous negotiation of the identities of academic authors as well as those of other people constitutes an intricate part of network formations. Identities are always 'footed' in relation to other identities. For example, the academic star would be nothing without her followers, and vice versa. The development of philosophy – as those of other disciplines and cultures – is heavily shaped by shifting network constellations.

Generally, the adoption and attribution of identities is a risky and shaky process. As identities are relational, the adoption of one identity relies on others to play their part – as in the case of the academic leader and her followers. The unilateral adoption of any identity confers power to the other party to accept or reject the claim. For example, in the beginning of a romantic interaction, neither party may want to appear more or less committed to the interaction. A signal of greater commitment from one person leaves open the possibility that the other person signals less commitment awarding more power to that person. In such situations, identities (and their relations to each other) emerge in the course of inherently ambiguous interactional sequences.

The emergence of a collective identity (as among the workers and nonworkers in the Paris Commune studied by Roger Gould, 1995) similarly relies on and triggers a particular structure of social networks. These have to be highly divided along this partition. In turn, the symbolic identification of this partition foments greater social conflict and reinforces categorical differences, thus fostering network segregation.

2. Identities are defined and related to each other in *stories* (White, 2008: pp. 26ff.; Somers, 1994). These stories fluctuate in network ties, but they also structure them. They formulate accounts of the qualities and the dispositions of the actors involved and of their relations to other actors, coalescing into a meaningful, but contested description of the network. In turn, this 'phenomenological reality of the network' structures interaction in the network by rendering particular interactions likely and others unlikely (Fuhse, 2009: pp. 52f.).

For example, if a network features a story of how A cheated on B, this will affect how A and B behave toward each other and others behave toward them. B will be seen as hurt and easily fooled. Others might offer consolation or help against A's action. A will be seen as not trustworthy. Therefore others will probably shy away from engaging in risky enterprises with him or her. B might try to retaliate (with or without the help of others), and A could try to make it up to B, if only to regain a reputation of trustworthiness. Now all of this was presented as if A, B, and the others were rationally calculating agents, making sense of the situation and reacting to it accordingly. According to White, Tilly, and Fuchs, the behavior of the identities involved follows more from circumstances than from calculation and dispositions (Fuchs, 2001: pp. 251ff.). The overall process can thus be attributed to the actions of the identities involved, or seen as recalibration of the network, following the implications of such stories, both in structure and in the construction of meaning.

Everyday storytelling generally adopts an action-theoretical perspective: Events are accounted for as the results of deliberate individual actions, driven by inner motives and interests (Tilly, 2002: pp. 26ff.). As in the example above, such everyday storytelling leads to the construction of identities on the basis of assumed personal qualities (easily fooled) and inner motives (selfish); they are related to each other when these dispositions are directed at particular other identities (B's cheating reveals a lack or a loss of personal interest in A); and they often relate more than two actors to each other, structuring not only dyadic relationships (between A and B) but also constellations (A, B, C, and D). And stories are dually relational by not only linking actors to actors, but more directly events to other events. In any case, such relational stories reduce social contingency by making particular interactions likely and others unlikely.

Stories affect interactions through the formation of expectations (see Section Conceptualizing Meaning). Stories about events lead to expectations about future events – and it is these expectations that effectively condition future events. It is not necessary to conceptualize these expectations as individual and subjective: The expectations are part of the network – they are the meaning of the network; and individuals adopt these expectations and routinely conform to them. Such expectations can develop in the network out of observing events. But they can also derive from institutionalized cultural repertoires, as in the case of relationship frames.

3. Even though social network analysis has often bracketed the question of relational content, opting instead for a binary representation of zeroes and ones, the *type of tie* connecting individuals has always been relevant. That is, individuals are not simply related to one another, but rather related in particular ways – through friendship, advice, economic transactions, sexual intercourse, dating, etc. The type of tie has important and significant implications for network structure and outcomes. Friendship ties, for example, are likely to be reciprocal (if I am your friend, then you are mine) and closed (you are likely to be friends with your friend's friends). Romantic ties, on the other hand, typically defy such extended closure – if person A is romantically involved with both B and C, it is unlikely that B and C are also romantically linked.

The distinction between these types of tie is a symbolic one. Friendship ties are different from romantic ties by virtue of the cultural expectations tied to these. Friendship and love are cultural models (*relationship frames*) for ties. Such models vary over time and social context (Yeung, 2005). They prescribe what people can expect of one another in these relationships, and they suggest a particular structuring of social relations around the tie in question. For example, love relationships are expected to remain exclusive, but also to mesh in the couple's respective friendship networks. Thus, the meanings associated with singular relationships have consequences for their network structure.

Because such meanings are continuously in flux, relational structure also has to be conceived of as dynamic rather than static. For example in Renaissance Florence, patronage seekers discursively frame relationships drawing on cultural models like 'honor,' 'friendship,' 'affection,' and 'service' in the hopes of building networks and gaining favor (McLean, 2007). The use of these discursive framing techniques come from already achieved positions in networks but also alter existing relational structures.

While any given relationship may be based upon cultural blueprints, communication between interactants will also lead to modification of those expectations. Relationships may also switch between frames. Such changes in the meanings of relationships have cascading effects, altering the structure of networks in which those ties are embedded. In a group of friends, for example, the breaking up of one romantic relationship may put strains on other ties as well. In similar spirit, while many relationships can be defined by type (such as love or friendship), others may not be amenable to such stable categorization. A given relation may be imbued with different meanings by different network participants. This diversity in tie-meaning has implications for the network's micro- and macrostructure and can be linked to actors' differential exposure to distinctive social contexts and differential embeddedness of their ties in other networks (Gondal and McLean, 2013).

4. Individual identities, stories, and relationship frames will be strongly affected by the partitioning of the identities in a network by *social categories.* In school classes, friendships predominantly form within-gender, love relationships (still) mostly cross-gender. Thus if A asks B to go to the movies together, this will be seen very differently if they belong to the same gender or not, evaluating this behavior against typical scripts for the categories involved. The same holds true if A happens to be the teacher and B a pupil.

Categorical ascriptions shape the identities adopted by and attributed to actors, thus reducing interactional uncertainty and affecting the storytelling about particular events. But it also directly impinges on the probabilities of events to take place at all. A is unlikely to ask B to go to the movies if B is in a (heterosexual) relationship with C *and* of the opposite sex to A. Similar interactional norms often apply to interracial or interethnic relationships. Categories like ethnic descent or gender thus make for a patterning of social ties (Tilly, 1998: pp. 62ff.). This patterning can lead to constellations where categories divide a network into *cohesive subgroups*. Ethnic categories, for example, usually increase the probability of forming intraethnic personal relationships. Interethnic relationships, in contrast, are unlikely.

This propensity of forming personal relationships within a category is called 'homophily' (McPherson et al., 2001). However, this tendency is often supported by other factors, for example, when minorities live in separate neighborhoods without much interethnic contact to start from, or when minority members share similar cultural traditions and values that increase the likelihood of forming personal relationships. In general, social categories that bound densely connected subgroups allow them to bar outsiders from resources and opportunities – a mechanism Charles Tilly terms 'opportunity hoarding' (1998: pp. 153ff.).

The genders also form interaction groups, but only when we consider friendship ties. These are mostly confined to same-sex relationships, especially among adolescents in school classes (studied in much network research). Love relationships,

however, are predominantly cross-gender. Categories thus do not necessarily separate cohesive subgroups. Rather they structure networks into positions of *structural equivalence*, with subgroups as a special case. For example, the category 'tenant' circumscribes a position in feudal social structure. But tenants are rarely connected – they resemble each other not in their connectivity, but in their relations to the nobility. We see here that categories are related to each other by specific types of tie – the relationship frames of 'friendship,' 'love,' and 'feudal tenure' imply a specific network constellation between the categories related by them (Fuhse, 2009: pp. 62f.).

Not only individuals, but also collective and corporate actors are positioned in networks by category. For example, the network of public discourse allocates very different roles to political parties, to social movements, to unions and churches, and to corporate interest groups. Whether a collective actor gets classified as a voluntary organization or as a corporate interest group has a great impact on their relations to other corporate and collective actors. Therefore this classification is frequently contentious. As with other forms of meaning, social categories for actors in networks are often derived from institutionalized cultural repertoires. But they can also develop in the network to map network positions by appropriate categories like subcliques or hangers-on. Once in place, social categories tend to stabilize relations of structural equivalence in networks.

These considerations lead back to the concepts of roles and institutions. Recall (from Section Meaning in Social Network Analysis) that institutions have been defined as habitually perpetuated, typified rule-systems governing the behavior of actors toward one another. *Roles* in networks such as subcliques or hangers-on are classified into categories, as soon as names or other symbols for these roles develop. These categories institutionalize to the extent that they crystallize as meaningful descriptions of roles and relations across network contexts. Such institutions provide cultural blueprints for the expectations attached to actors of a particular category, thus bearing an imprint on network patterns.

For example, the gender category is an institution that governs the formation of social constellations in a wide variety of social contexts. However, the precise meaning of gender, and of other institutions (and the resulting network structure), can vary considerably by context, for example, by region, class, age, ethnic group, organization, etc.

Apart from role categories, such institutions can entail expectations about relationship formation (relationship frames), or even constellations of a number of roles, for example, family roles in a kinship network. Roles and relationship patterns in a network form local structures that are often heavily imprinted by wider cultural models.

5. A last form of meaning to consider is *styles*. In art, as in science, fashion, or in politics, the notion of styles designates recognizable bundles of symbols as distinct from other styles (White, 2008: pp. 112ff.). Styles often emerge from dense contact within a subclique of a network, symbolically separating this subclique from other groups and individuals. Historical examples from art include impressionism, expressionism, Dadaism, and almost any other art school. The style here acts as the 'culture' of the network, forming a repertoire of symbols shared within the clique. This basic view has to be appended here in three regards, leading from culture to relational meaning:
   a. Art schools like impressionism or expressionism always developed against other artistic traditions (White, 1993). Their styles not only unified the network of the subclique, but also separated it from and related it to an overall network configuration of contending styles and schools in the field of art. The same holds true for many other fields: science, fashion, politics, etc. Styles symbolize as much about identity as difference.
   b. New styles – creativity – seldom develop from scratch, simply out of increased internal contact of a group. Rather, styles from different network clusters are routinely tried for combination at their intersection in networks, bridging 'structural' as well as 'cultural holes' (Collins, 1998: pp. 131ff.; Pachucki and Breiger, 2010). These attempts only crystallize to form a new style if a new clique clusters around it, forming a new subclique separate from the two (or more) clusters from which it emerged.
   c. Styles do not always pertain to cohesive subcliques. They can also correspond to network position, especially if the stylistic identity (and difference) concerns relational practices. Ann Mische demonstrates in her work on Brazilian youth movement how leaders develop specific styles depending on whether they are firmly embedded in one social movement, or whether they bridge several movements (2008: pp. 241ff.). Thus the structural equivalence of network position in different context can make for stylistic differences.

Conclusion

Meaning in networks can be studied in different ways (Fuhse and Mützel, 2011). 'Qualitatively,' it has been analyzed on the basis of rich ethnographic work, on the basis of observations and archival data, or on the basis of in-depth interviews. Yet, meaning also has a tradition of being studied 'quantitatively' in social network analysis. Here, cultural networks between forms of meaning (e.g., concepts) are constructed out of documents or interviews, and analyzed using formal techniques of social network analysis. A prominent technique used by many authors (John Mohr, Charles Tilly, Peter Bearman, Ron Breiger, John Levi Martin, and Paul DiMaggio) is blockmodeling, identifying 'roles' of concepts or other forms of meaning in relation to each other. Other formal analytical methods used to study networks of meaning include Galois lattices (Yeung, 2005) and exponential random graph models (Gondal, 2011).

Overall, this 'cultural turn' in sociological network research leads to a view where network structures are much more than coagulations of 0s and 1s. Rather, they are seen as composed of relations laden with meaning, of nodes that, while embedded in cultural and resource contexts, have identities and roles that are endogenously constructed in a dynamic process of network formation, and whose behavior is often strategic and steeped in interpretive work. This general perspective has been fruitfully applied in a wide variety of social contexts, yielding important advances in the fields of economic and historical sociology,

social movement studies, social inequality, research on institutions, and the sociology of science.

Recent advances in the field point to the importance of microprocesses of interaction or communication in the development, stabilization, and change of social networks. In particular, how roles and other forms of meaning crystallize in conjunction with network structures in the course of communication (Gibson, 2005) and how networks as sociocultural configurations change over time are important themes. Drawing on recent advancements in the modeling of social networks – like exponential random graph models – distinct mechanisms that lead to the construction of networks can be evaluated. For example, these models can be useful for parsing the effects of different types of homophily (gender, race, ethnicity, etc.) from other mechanisms of category-based clustering such as triadic closure in the analysis of, say, school friendships. As before, the development of relational sociology progresses in close conjunction with complex theoretical models and elaborated empirical studies.

Abstract

Geography's recent post-structuralist turn has included a pronounced emphasis on relational conceptions of space. Central to this shift has been the use of networks to conceptualize geographical relations in an age of ferocious globalization and time–space compression. Empirically, networked geographies have been most commonly found in the analysis of economic issues. This article outlines several approaches to the theorization of networks: the rhizomes of Deleuze and Guattari, Latour's actor-network theory, the space of flows as put forth by Castells, commodity chain analysis, and Massey's power-geometries.

Economic, political, and cultural geographers, in acknowledging the massive changes unleashed by post-Fordist capitalism and flexible production, have increasingly emphasized mobilities, flows, and networks as the defining features of contemporary spatiality rather than discreet locales (Larsen et al., 2006). As a result, absolute conceptions of space have largely given way to relational perspectives, particularly concerning the space economy (Ettlinger, 2001; Bathelt and Glückler, 2003; Yeung, 2005; Glűckler, 2007; Sunley, 2008). Networks have become significant in analysis of flows of information, knowledge, and technologies over space and time, transnational corporations, globalization, commodity chains, transportation patterns, and the Internet. Other topics including social networks, and networks associated with differential spatial development.

This change in perspective has important intellectual and political ramifications. As Kirby (1996, p. 71) put it, "The distinctions between widely separated geographical entities lose their meaning as disparate sites themselves come together in a plastic network making proximity and separation relative and mutable." Relational space "is seen as an undulating landscape in which the linkages established in networks draw some locations together while at the same time pushing others further apart" (Murdoch, 2006, p. 86). Taken to the extreme, Doel (1999) follows Deleuze and Guattari in emphasizing the origami-like nature of space as it is repeatedly folded and refolded, fissured, cracked, and fractalized through a series of difference-producing repetitions.

If surfaces were the predominant metaphor that defined the geographies of modernity (e.g., the nation-state, urban commuting fields), their postmodern, post-structuralist equivalent is networks (Warf, 2008), which Ruggie (1993, p. 141) compares to the "economic equivalent of relativity theory." Geographies in this reading exhibit a "fibrous, thread-like, wiry, stringy, ropy, capillary character that is never captured by the notions of levels, layers, territories, spheres, categories, structures, or systems" (Paasi, 2004, p. 541). It is no coincidence that the discovery that space is socially produced, and the shift to relational space, arose in tandem with mounting emphasis on networks. The spatiality of surfaces and regions buttressed assumptions that space was fixed and given, asocial in character. Networks, in contrast, call attention to the social origins of spatial relations, the power interests vested in them, and their political consequences. Networks have been central to ushering in views of geography as topological and non-Euclidean in nature. For example, globalization, in linking spatially separated producers and consumers, has, in Sheppard's (2002) view, created global power-geometries that transcend rigid hierarchies of spatial scale to generate 'wormholes' that connect widely separated places in complex and often unexpected ways. Not coincidentally, the invocation of networks has accompanied geography's mounting intellectual respectability and the 'spatial turn' that has unfolded across numerous social sciences and humanities.

The analysis of space via networks has a remarkably long, if unacknowledged, history. This article charts the intellectual foundations of this process, beginning with the seminal works of Deleuze and Guattari. Next, it charts the dimensions and spatiality of actor-network theory as it originated in the works of Bruno Latour and Michael Serres. Third, it points to two explicit ways in which networks penetrated the discipline of geography, Castells's space of flows, commodity chain analysis, and power-geometries conceptualized by Doreen Massey. It should be emphasized that no uniformity of opinion exists regarding the nature and importance of networks. While most of these perspectives draw from post-structuralist accounts of space, knowledge, and power, there are important differences among them. However, to varying degrees, all of these lines of thought portray geographies in terms of the relational linkages among places rather than absolute location; they share a common concern that space is defined functionally rather than in terms of physical distance; and all transcend the traditional notion of spatial scale as fixed and given. In short, networks call attention to the ontology of relations rather than things.

Deleuze and Guattari: Geography as Rhizomes

Despite the notorious complexity of their writing, Deleuze and Guattari (1987) in many respects pioneered early notions of relational space. Their work suggested a self-consciously 'schizophrenic' view of space that foregrounds movement and constant flux rather than the usual dimensions of distance and direction.

In this conception, social and spatial relations may be traced to the rise of the state during the Neolithic era, in which geographically fixed agricultural societies began to tame and

dominate surround nomadic tribes roaming the surrounding plains. For Deleuze and Guattari, the state embodies all the essential characteristics of class society, including stability, hierarchy, control, classes, and the extraction of surplus value. As a result it produces striated spaces that are ordered and bordered, and thus easily controlled. The territories of the state are essentially arboreal in nature, defined by roots and nested scales and layers, all of which are amenable to panopticonic control. Intimately associated with this process were the construction of time as a linear sequence and the rise of what they call 'arboreal thought' that privileges one vantage point over others. Given their anarchist tendencies, class society and striated spaces are intimately associated with the reigning in of desire, or control over human subjects. In contrast, they juxtapose an idealized model of nomads and nomadic life. Whereas the state represents, for them, stasis and being (in the Aristotelian sense), nomads are paragons of unstructured flows, free movement, and becoming (in the way suggested by Heraclitus). Nomadic life produces what they call smooth spaces that are not easily controlled, allowing desire to unfold unfettered, and affirming the centrality of location in the generation of multiplicity, plurality, variation, and difference. Smooth nomadic space is folded, like origami, as agents produce and reproduce their worlds. Such a view emphasizes space as emergent, forever coming into being through connections, flows, interactions, and movements.

Deleuze and Guattari's most famous geographical contribution was the model of the rhizome, the network with no clear core or periphery, with multiple entry points and exits. Rhizomes exist in nature, of course, including fungi, crabgrass, potatoes, rodent burrows, ant colonies, and the synapses of the brain. Social equivalents are not hard to find, including terrorist networks, traffic jams, patterns of diffusion, and the Internet. Knowledge, too, is rhizomatic, ranging from the circulation of gossip to their condemnation of psychoanalysis as arboreal (and the suggestion that 'schizoanalysis' is emancipatory). The DeleuzeGuattarian sense of rhizomes is deeply political, as they are intimately associated with a world devoid of centralized political control, one in which desire is untamed, allowing emergent possibilities to come to fruition. Rhizomes in this light are arenas in which the possible becomes the actual, spheres of becoming rather than being: they blur the line between what is and what might be. Echoes of this way of thinking can be found in the literature on complex adaptive structures, self-organizing systems, and the path dependencies of evolutionary economics. The metaphor of the rhizome, so different from the transparent spaces of Euclideanism, views of space as interconnected sets of networks that are nonhierarchical in nature, in which connections among locales rather than their absolute positionality is the dominant characteristic.

Actor-Network Theory

A second pillar in the emergence of network models of space is actor-network theory (Murdoch, 1997, 1998; Law and Hassard, 1999). Inspired by the work of Bruno Latour (1993) and Michael Serres (1997) (see also Serres and Latour, 1995), actor-network theory incorporates sociological understandings of structuration theory (Giddens, 1984) with a post-structuralist social constructivist philosophy of science (Bingham and Thrift, 2000). Actor-network theory departs from the Enlightenment focus on dualities such as individual and society, people and nature, human and nonhuman, Western and non-Western, urban and rural, micro and macro, local and global. Rather, it takes as its point of departure the linkages among these categories rather than their essences as actors draw upon and combine them in various forms of hybridity.

Actor networks involve the mobilization of rules, resources, and power, including information, in order to accomplish tasks, creating a net of intended and unintended consequences that stretch across the spatiotemporal boundaries of the network. To maintain network functionality, actors must perform by being engaged with one another recursively, interpreting and translating one another's behavior. Actors and networks are thus twin, mutually presupposing aspects of one phenomenon, simultaneously enabling and constraining actions in time and space. Thus, it is not simply actors in everyday life who constitute the primary focus here, but their relative positionality and powers within integrated systems of power and information that matter most. Such a perspective has helped to humanize even the most abstract of economic processes by revealing them to be the products of agents enmeshed in webs of power and meaning, not disembodied processes that operate independently of the people who create them (Law, 1994). The strategy of embodiment goes a long way toward demythologizing teleological interpretations of globalization, which present it as natural and inevitable, and reveal global processes to be the contingent outcomes of decisions made by human actors tied up in networks that cross multiple spatial scales.

Actor-network theory generated considerable controversy because of the view it offered of humans as actors. In reducing people to positions in networks, critics allege that it was deeply antihumanistic in nature, denying any causal power to consciousness and robbing people of any ability to shape the world. 'Agency,' in this reading, is distinct from consciousness: actors have effects, and their intentions are essentially irrelevant. Moreover, because actor-network theory strives to overcome the artificial boundaries between culture and nature (Latour, 1993), actors in this sociotechnical seamless 'nature-culture' nexus need not be human, but may include inanimate objects such as books, papers, or computer systems (Bingham, 1996; Murdoch, 1997), which are necessary to the maintenance and operation of networks. For example, in order for a bank or other corporation to function, people within them must operate in interaction with computers, documents, buildings, and other objects: privileging the human over the nonhuman makes no sense. Actor-network approaches thus challenge the long-standing anthropocentrism of the social sciences, opening conceptual space for actors to be animals or things.

Because actor networks are deeply spatial, they offer important implications for spatial analysis. Such a view elides the conventional focus on spatial scale, for networks operate across many scales simultaneously, creating as Latour (1993, p. 121) put it, "an Ariadne's thread that allows us to pass with continuity from the local to the global, from the human to the nonhuman. It is the thread of networks of practices and instruments, of documents and translations." By forcing us to rethink how time and space are produced – that is,

topologically rather than in terms of conventional Cartesian and Kantian views of space that have dominated geography – actor-network theory becomes "a machine for waging war on Euclideanism" (Law, quoted in Murdoch, 1998, p. 357). Not surprisingly, this view has become popular among those advocating a 'flat ontology' devoid of scale (Marston et al., 2005) and relational views of space (Murdoch, 2006). Scale, in this view, is constructed, not given, and represents only varying lengths and sizes of actor networks. Distinctions such as global and local lose their significance: Latour famously asked, for example, whether the trains he saw from his Parisian office were 'local' or 'global.' The answer, of course, is that they are both. Like all post-structuralist views, actor-network theory rejects either/or dichotomies in favor of inclusive both/and views that celebrate hybridity.

The Space of Flows

One of the earliest and more influential steps toward a geography of networks was the space of flows proposed by Manuel Castells (1996, 1997). This analysis distinguished earlier *information* societies, in which productivity was derived from access to energy and the manipulation of materials, from later *informational* societies that emerged in the late twentieth century in which productivity is derived primarily from knowledge and information. In his reading, the time–space compression of postmodernism included the three overlapping layers of transportation and communication infrastructure, the cities or nodes that occupy strategic locations within these networks, and the social spaces produced by the global managerial class:

> Our societies are constructed around flows: flows of capital, flows of information, flows of technology, flows of organizational interactions, flows of images, sounds and symbols. Flows are not just one element of social organization: they are the expression of the processes dominating our economic, political, and symbolic life. … Thus, I propose the idea that there is a new spatial form characteristic of social practices that dominate and shape the network society: the space of flows. The space of flows is the material organization of time-sharing social practices that work through flows. By flows I understand purposeful, repetitive, programmable sequences of exchange and interaction between physically disjointed positions held by social actors.
>
> 1996, p. 412

For Castells (1996, p. 470), the space of flows consists of a series of overlapping rhizomatic networks: "Networks are appropriate instruments for a capitalist economy based on innovation, globalisation, and decentralised concentration; for work, workers and firms based on flexibility; for a culture of endless deconstruction and reconstruction; for a polity geared towards the instant processing of new values and public moods; for a social organisation aiming at the supersession of space and the annihilation of time." He argues, for example, that while people live in places, postmodern power is manifested in the linkages among places, their interconnectedness, as personified by business executives shuttling among global cities and using the Internet to weave complex geographies of knowledge invisible to almost all ordinary citizens. This process was largely driven by the needs of the transnational class of the powerful employed in information-intensive occupations; hence, he writes (1996, p. 415) that "Articulation of the elites, segmentation and disorganization of the masses seem to be the twin mechanisms of social domination in our societies." Flows thus consist of corporate and political elites crossing international space on transoceanic flights; the movements of capital through telecommunications networks; the diffusion of ideas through organizations stretched across ever-longer distances; the shipments of goods and energy via tankers, container ships, trucks, and railroads; and the growing mobility of workers themselves. In this light, the space of flows is a metaphor for the intense time–space compression of post-Fordist capitalism. Through the space of flows the global economy is coordinated in real time across vast distances, i.e., horizontally integrated chains rather than vertically integrated corporate hierarchies. In the process, it has given rise to a variety of new political formations, forms of identity, and spatial associations.

Flows by definition involve more than one place; hence, in a networked world, places have little meaning as isolated entities. Places are not locales as much as they are processes in which different types of activities are embedded and different forms of interconnection are established. As they become increasingly connected, the repercussions of actions in one area inevitably spiral out to shape other places, so that discreet boundaries have less and less significance as they are permeated with mounting ease. Decisions made by hedge fund managers in New York, for example, reach out to affect the lives of millions of people in locations as distant as East Asia. The space of flows wraps places into highly unevenly connected chains that center on connections among powerful elites, thus typically benefiting the wealthy at the expense of marginalized social groups. However, such networks are hardly randomly distributed over the earth's surface: rather, it reflects and reinforces existing geographies of power concentrated within specific nodes and places, such as global cities, trade centers, financial hubs, and headquarter complexes. Thus, far from being abstract networks divorced from history, such systems are only made comprehensible by embedding them in history (Cresswell, 2006).

Central to the rise of globalized, postmodern capitalism was the construction of a vast web of telecommunications networks, which were crucial to the hegemony of increasingly information-intensive capitalism. The core of the global telecommunications infrastructure is a seamless network of fiber-optic lines that serve as the backbone of the Internet, a geographical network *par excellance*. Because the implementation of fiber lines reflects the powerful vested interests of international capital, these systems may be seen quite literally as 'power-geometries' (Massey, 1993, 1999) that ground the space of flows within concrete material and spatial contexts. Financial services firms were at the forefront of the construction of high-capacity fiber networks in large part because they facilitated the use of electronic funds transfer systems, which comprise the nervous system of the international financial economy, allowing banks to move capital around a moment's notice, arbitrage interest rate differentials, take advantage of favorable exchange rates, and avoid political unrest. Cyberspace allows for the reconstruction of 'communities without

propinquity,' groups of users who share common interests but not physical proximity, although the ability of virtual communities to substitute for face-to-face ones is debatable. The implications of this process are sobering. As Graham and Aurigi (1997, p. 26) note, "Large cities, based, in the past, largely on face-to-face exchange in public spaces, are dissolving and fragmenting into webs of indirect, specialized relationships." More generally, cheap, instantaneous, and ubiquitous communications have increasingly made the notion of place as a discreet, bounded entity increasingly problematic by allowing people to be in several places simultaneously. In this context, absolute distance is much less relevant than relative distance, i.e., space measured in terms of time, cost, and social access. Conventional geographic preoccupations with proximity mean little in this case, for the topologies of global finance are formed and deformed at the speed of light in ways that the language of location theory cannot capture.

Commodity Chains

Another step in the theorization of space as networks is the notion of commodity chains (Gereffi and Korzeniewicz, 1994; Dicken et al., 2001; Bair, 2005). Drawing from the earlier French tradition of *filieres* or value chain analysis, commodity chains may be defined as networks of labor and production processes that give rise to a particular commodity from raw material to processing, delivery, and consumption. Commodity chains include flows of goods and information among different points or nodes, varying labor relations across the length of the chain, and different constellations of production and governance at each segment. Such tools are useful in dissecting, for example, the spatiality of transnational corporations. Under globalization, commodity chains became increasingly larger in scope and length, linking widespread places through an increasingly complex division of labor in which distant strangers became ever more reliant upon one another.

Gereffi (1996) famously distinguished between producer-driven and buyer-driven chains, in which the power to control transactions lay at different ends of the concatenated linkages. In overcoming the artificial separation between production and consumption, commodity chains help to expose the widespread commodity fetishism prevalent in advanced economies, exposing commodities, *a la* Marx, as more than just things but as embodiments of social processes and thus helping to expose the unequal power relations among places that lie in the creation of goods. Chains are hence simultaneously geographical, economic, political, and cultural. They lie at the boundaries of the tangible and the intangible, incorporating sets of meanings, or as Hartwick (1998, p. 424) elegantly put it, they "conjoin the representational with the geomaterial." Moreover, they are temporally situated, constantly fluctuating in location, composition, and length over time.

Power-Geometries

Drawing upon, overlapping with, and advancing the view of geography as networks is the enormously influential work of Doreen Massey (1993, 1999, 2005). Massey scathingly criticizes traditional notions that represent places as islands of stability in the constantly shifting oceans of capitalist change, arguing that in minimizing the interconnectedness of peoples and places such a characterization is reactionary. Networks, in contrast, highlight how changes in one location reverberate to shape other locations. Instead, Massey promotes a progressive sense of place that firmly links places to other places, a view in which places constantly change, producing and receiving changes through their constant, simultaneously determinant interactions with one another. A relational politics of place calls into question easy distinctions like inside/outside, near/far, space/place, and global/local, artificial differentiations that are always embedded in each other and mutually constituted.

More recently, Massey (2005) argues passionately that Cartesian conceptions of space as a passive surface inevitably deemphasize the temporal flux that are always an inherent part of geographies, and simultaneously create a false dichotomy between the local and the global. As an alternative, she suggests three maxims: (1) that space be seen as the product of interrelations, i.e., of embedded social practices in which identities and human ties are coconstituted; (2) that space be understood as the sphere of multiple possibilities, i.e., as a contingent simultaneity of heterogeneous historical trajectories; and (3) that space must be conceived as always under construction, in the process of forever being made, implying a continual openness to the future. These steps are fundamental to an appreciation of the deeply political nature of geography: "Conceptualising space as open, multiple and relational, unfinished and always becoming, is a prerequisite for history to be open and thus a prerequisite too, for the possibility of politics" (p. 59). This line of thought goes far to injecting an explicit concern for politics in the perspective of geography as networks.

Conclusions

Post-structural geography, in emphasizing the embodied nature of social life as situated practices, drew attention away from Euclidean conceptions of space as an inert container and toward interconnected sets of places as manifolds that are continuously folded and pleated, stretched, distorted, and shredded. This perspective has served to underscore how, unlike traditional chorology, with its emphasis on static places, relational geographies are always dynamic, incomplete, forever coming into being, and perpetually in flux, giving rise to ever-changing patterns of centrality and peripherality. Geography consists of the contingent networks or power-geometries generated by social interaction rather than a homogenous plane that preexists coherent, well-ordered societies. In short, space is emergent rather than existing a priori, it is composed of relations rather than structures.

Theorizations of networks take many forms, but all of them share, to one degree or another, an emphasis on the interconnectedness of places and peoples. In so doing, network geographies help to circumvent deeply entrenched dualities such as global/local that tend to reify spatial scale and obfuscate the political dynamics at work in the reproduction of uneven development. Globalization, for example, can be fruitfully

theorized as a series of long actor-networks that transcend political borders and render scale obsolete, or as commodity chains that unite producers, consumers, and intermediaries, calling attention to the ways in which some places shape others. In an age of intense, rampant time–space compression, networks are a useful and meaningful way of theorizing the social production of space in all its messy complexity, sidestepping conventional infatuations with proximity.

Abstract

We provide an overview on networks in economics. We first look at the theoretical aspects of network economics using a game-theoretical approach. We derive some results on games on networks and network formation. We also study what happens when agents choose both links and actions. We then examine how these models can be used to address some applied and empirical relevant questions by mainly focusing on labor market networks and crime networks. We provide some empirical evidence on these two types of networks and address some policy implications of the models.

Introduction

The study of social networks was initiated by sociologists more than a century ago and has grown to be a central field of sociology over the past 50 years (see, e.g., Wasserman and Faust, 1994). Over that same period, a mathematical literature on the structure and properties of graphs has been developed and extensively studied (see, e.g., Bollobás, 1998). A recent awakening of interest in social networks has occurred in the computer science and statistical physics literature, mainly over the past 15 years (see Albert and Barabási, 2002; Newman, 2010; for an overview of these studies). While the importance of embeddedness of economic activity in social settings has been fundamental to sociologists for some time, it was largely ignored by economists until the last decade. This is surprising given that nonmarket interactions, i.e., interactions between agents that are not mediated by the market, are crucial to explain different economic phenomena such as stock market crashes, growth, education, religion, crime, etc. The studies of networks with economic perspectives and using game-theoretic modeling techniques have only emerged over the last decade (see Goyal, 2007; Jackson, 2008).

In the present article, we would like to survey the recent literature on networks in economics. As in all surveys and because of space constraint, we will not be able to cover all aspects of the literature and therefore we refer to other overviews such as Goyal (2007), Jackson (2008), de Martí and Zenou (2011) and Jackson and Zenou (forthcoming). (See also Jackson and Zenou (2013) for a collection of the most important published papers in the economics of networks.) We will expose what we believe are the most important aspects of the economics of networks and will illustrate each aspect by a simple theoretical model.

This article is divided in two parts. In the first one, we will look at the theoretical aspects of network economics using a game-theoretical approach. In this part, we will look first at games on networks, which take networks as given and focus on the impact of their structure on individuals' outcomes. We will then analyze network formation and explain the way links between agents are formed. We will also study what happens when agents choose both links and actions. In the second part of this paper, we will see how the theoretical models can be used to address applied and empirical relevant questions. We will mainly focus on labor-market networks and crime networks. We will also provide some empirical evidence on these two types of networks and address some policy implications of the models.

Networks in Economics: Theoretical Aspects

Games on Networks

We begin with a class of canonical and widely applicable games; specifically, games where there is a fixed and given network of interactions. Links indicate which players' strategies affect which others' payoffs. In particular, a given player's payoff depends only on the play of the neighbors. Of course, this still results in network effects since there may be chains of influence.

Network definitions

We provide some basic definitions on networks.

A set of players $N = \{1,\ldots, n\}$ are connected by a network.

A graph or network is a pair $(N, \mathbf{g})$, where $\mathbf{g}$ is a network on the set of nodes N. To each network $\mathbf{g}$, we associate its adjacency matrix $\mathbf{G} = [g_{ij}]$. A graph is undirected if $\mathbf{G}$ is required to be symmetric so that $g_{ij} = g_{ji}$, and is directed otherwise. It is useful to use the notation $ij \in \mathbf{g}$ to indicate that $g_{ij} = 1$ and $ij \notin \mathbf{g}$ to indicate that $g_{ij} = 0$, and one can represent a graph by the set of links that are present (so one could alternatively represent $\mathbf{g}$ by its set of links). A weighted adjacency matrix, $\mathbf{G}$, is when g_{ij} can take values other than 0 and 1.

A relationship between two nodes i and j, represented by $ij \in \mathbf{g}$, is referred to as a link. Links are also referred to as edges or ties in various parts of the literature, and sometimes also directed links, directed edges, or arcs in the specific case of a directed network.

A walk in a network $(N, \mathbf{g})$ refers to a sequence of nodes, i_1, i_2, $i_3,\ldots, i_{K-1}$, i_K, such that $i_k i_{k+i} \in \mathbf{g}$ for each k from 1 to K. The length of the walk is the number of links in it, or $K - 1$. A path in a network $(N, \mathbf{g})$ is a walk in $(N, \mathbf{g})$, i_1, i_2, $i_3,\ldots, i_{K-1}$, i_K, such that all the nodes are distinct.

The distance $d(i, j)$ between two nodes i and j in the same component of a network is the length of a shortest path (also known as a geodesic) between them.

The neighbors of a node i in a network $(N, \mathbf{g})$ are denoted by $N_i(\mathbf{g})$, so that

$$N_i(\mathbf{g}) = \{j | ij \in \mathbf{g}\}$$

The degree of a node i in a network $(N, \mathbf{g})$ is the number of neighbors that i has in the network, so that $d_i(\mathbf{g}) = |N_i(\mathbf{g})|$. Unless otherwise stated, let us suppose that $g_{ii} = 0$, so that nodes are not linked to themselves.

The kth power $\mathbf{G}^k = \mathbf{G}^{(k \text{ times})}\mathbf{G}$ of the adjacency matrix $\mathbf{G}$ keeps track of indirect connections in $\mathbf{g}$. More precisely, the coefficient $g_{ij}^{[k]}$ in the (i, j) cell of $\mathbf{G}^k$ gives the number of paths of length k in g between i and j. In particular, $\mathbf{G}^0 = \mathbf{I}$. Note that, by definition, a path between i and j need not follow the shortest possible route between those agents. For instance, when $g_{ij} = 1$, the sequence $ij \rightarrow ji \rightarrow ij$ constitutes a path of length three in g between i and j.

Game on network definitions

When the network is fixed, there are two types of games: games with strategic complementarities and games with strategic substitutes. Let us define them formally. Players have effort spaces X_i and payoff functions $u_i = X_i \rightarrow \mathbb{R}$. The action spaces are finite sets or subsets of a Euclidean space. A given player's payoff depends on other players' behaviors, but in particular only on those to whom the player is connected in the network. More formally, i's payoff depends only on x_i and $\{x_j\}$ $X_j \in N_i$ (g) and can be written as $u_i(x_i, x_j)$, where $x_i \in X_i$ is the effort of player i. We have the following definitions.

A game exhibits strategic complements if it exhibits increasing differences, i.e., for all i, j, with $i \neq j$, $x_i \geq x_i'$ and $x_j \geq x_j'$:

$$u_i(x_i, x_j) - u_i(x_i', x_j) \geq u_i\left(x_i, x_j'\right) - u_i\left(x_i', x_j'\right).$$

A game exhibits strategic substitutes if it exhibits decreasing differences, i.e., for all i,j, with $i \neq j$, $x_i \geq x_i'$ and $x_j \geq x_j'$:

$$u_i(x_i, x_j) - u_i(x_i', x_j) \leq u_i\left(x_i, x_j'\right) - u_i\left(x_i', x_j'\right).$$

These notions are said to apply strictly if the inequalities above are strict whenever $x_i > x_i'$ and $x_j > x_j'$.

Because of the lack of space, we will only expose games with strategic complementarities since they have been more studied, have nice properties, and have nicer and more natural applications in economics. (Prominent papers studying games with strategic substitutes are Bramoullé and Kranton (2007) and Galeotti and Goyal (2010). For an overview of the literature on games on networks, see Jackson and Zenou (2013).)

A simple model with strategic complementarities

We assume perfect information, i.e., the players know everything about the network and other players' actions. For games on networks with incomplete information, see Calvó-Armengol and de Marti (2009), Galeotti et al. (2009), Hagenbach and Koessler (2011) and Acemoglu et al. (2011).

The game: Consider a game in which n agents, linked to each other in a network $\mathbf{g}$, must decide how much effort to exert in some activity. We denote by x_i the effort level of agent i and by $\mathbf{x} = (x_i, \ldots, x_n)^{\mathrm{T}}$ the vector of efforts of all agents (^{T} means transposition). Each agent i selects an effort $x_i \geq 0$, and obtains a payoff $u_i(\mathbf{x}, \mathbf{g})$ that depends on the effort profile $\mathbf{x}$ and on the underlying network $\mathbf{g}$, in the following way:

$$u_i(\mathbf{x}, \mathbf{g}) = ax_i - \frac{1}{2}x_i^2 + \phi \sum_{j=1}^{n} g_{ij}x_ix_j \qquad [1]$$

where a, $\phi > 0$. In this linear-quadratic utility function, agents are ex ante homogeneous in terms of observable characteristics (i.e., they all have the same a) and their heterogeneity only stems from their position in the network. The first two terms of eqn [1], $ax_i - (1/2)x_i^2$, give the individual benefits and costs of providing effort x_i. The last term of this utility function, $\phi \sum_{j=1}^{n} g_{ij}x_ix_j$, reflects the influence of direct links on own action. This peer effect component can be heterogeneous, and this endogenous heterogeneity reflects the different locations of individuals in the network $\mathbf{g}$ and the resulting effort levels. More precisely, bilateral influences are captured by the following cross derivatives, for $i \neq j$:

$$\frac{\partial^2 u_i(\mathbf{x}, \mathbf{g})}{\partial x_i \partial x_j} = \phi g_{ij} \geq 0 \qquad [2]$$

When i and j are directly linked, i.e., $g_{ij} = 1$, the cross derivative is $\phi > 0$ and reflects strategic complementarity in efforts. When i and j are not direct friends, i.e., $g_{ij} = 0$, this cross derivative is zero.

The Katz–Bonacich network centrality

Define

$$\mathbf{M}(\mathbf{g}, \phi) = (\mathbf{I} - \phi\mathbf{G})^{-1} = \sum_{k=0}^{+\infty} \phi^p \mathbf{G}^p$$

where $\mathbf{I}$ is the identity matrix. Denote by $\mathbf{1}$ the column vector of 1. We have the following definition:

Definition 1 (Katz, 1953; Bonacich, 1987): Given $\phi > 0$, a small enough scalar, the vector of Katz–Bonacich centralities of parameter ϕ in network $\mathbf{g}$ is defined as

$$\mathbf{b}(\mathbf{g}, \phi) = (\mathbf{I} - \phi\mathbf{G})^{-1}\mathbf{1} = \mathbf{M}(\mathbf{g}, \phi)\mathbf{1} = \sum_{p=0}^{+\infty} \phi^p \mathbf{G}^p \mathbf{1}. \qquad [3]$$

The Katz–Bonacich centrality of node i is thus $b_i(\mathbf{g}, \phi) = \sum_{j=1}^{n} m_{ij}(\mathbf{g}, \phi)$, and counts the total number of walks in $\mathbf{g}$ starting from i. It is the sum of all loops $m_{ii}(\mathbf{g}, \phi)$ from i to i itself, and of all the outer walks $\sum_{j \neq i} m_{ij}(\mathbf{g}, \phi)$ from i to every other player $j \neq i$, i.e.,

$$b_i(\mathbf{g}, \phi) = m_{ii}(\mathbf{g}, \phi) + \sum_{j \neq i} m_{ij}(\mathbf{g}, \phi).$$

By definition, $m_{ii}(\mathbf{g}, \phi) \geq 1$, and thus $b_i(\mathbf{g}, \phi) \geq 1$, with equality when $\phi = 0$.

Nash equilibrium

In game theory, the Nash equilibrium (named after the Nobel-prize winner John F. Nash) is a solution concept of a game involving two or more players, in which no player has anything to gain by changing only her own strategy (i.e., by changing unilaterally). If each player has chosen a strategy and no player can benefit by changing her strategy while the other players keep theirs unchanged, then the current set of strategy choices constitute a Nash equilibrium.

Let us now characterize the Nash equilibrium of the game where agents choose their effort level $x_i \geq 0$ simultaneously. Denote by $\mu_1(\mathbf{G})$ the spectral radius of $\mathbf{G}$. Ballester et al. (2006) have shown the following result:

Proposition 1: *If* $\phi\mu_1(\mathbf{G}) < 1$, the game with payoffs has a unique interior Nash equilibrium in pure strategies given by

$$\mathbf{x}^* = a\mathbf{b}(\mathbf{g}, \phi) \qquad [4]$$

This results shows that the Katz–Bonacich centrality is the right network index to account for equilibrium behavior when the utility functions are linear-quadratic. (There are many other centrality measures such as the betweeness or the closeness centrality. See Wasserman and Faust (1994) for an overview on the different possible centrality measures.) In eqn [1], the local payoff interdependence is restricted to direct network contacts. At equilibrium, however, this local payoff interdependence spreads all over the network through the overlap of direct link clusters. The Katz–Bonacich centrality precisely reflects how individual decisions feed into each other along any direct and indirect network path. The condition $\phi\mu_1(\mathbf{G}) < 1$ stipulates that local complementarities must be small enough compared to own concavity, which prevents multiple equilibria to emerge and, at the same time, rules out corner solutions. The condition $\phi\mu_1(\mathbf{G}) < 1$ also guarantees that $(\mathbf{I} - \phi\mathbf{G})$ is invertible and its series expansion well defined.

Proposition 1 has characterized the equilibrium effort x_i^* of each agent i as equals to the Bonacich centrality. We can now characterize the equilibrium utility of i as a function of the Bonacich centrality. It is easily verified that

$$u_i(\mathbf{x}^*, \mathbf{g}) = \frac{1}{2} x_i^{*2} = \frac{1}{2} [ab_i(\mathbf{g}, \phi)]^2$$

In other words, the equilibrium utility of each agent i is positively related to the Katz–Bonacich centrality.

Network Formation

In the previous section, we have seen how the position in the network of each player (i.e., the Katz–Bonacich centrality) affects outcomes when the network is fixed. We now look at network formation but agents cannot decide how much effort to exert in some activity. They only choose with whom they want to form a link.

Static models of network formation

Myerson (1977, 1991) provides an early formulation of a network formation game. The structure of the game is simple: agents have to decide about their potential partners and their strategies consist in naming those with whom they want to form a link with. For a link to be formed, it has to be that two individuals name each other, i.e., there needs to be mutual consent in link creation. The Nash equilibrium concept defined above can then be used to find out which strategy profiles are stable and, hence, which networks are the possible outcomes of the game.

The main problem of using the Nash equilibrium concept is that it exacerbates the coordination problems that arise when all agents are simultaneously deciding about links. In particular, the empty network (i.e., nobody forms a link) is always a Nash equilibrium of this game since no deviation is profitable. Indeed, deviating means here to name someone as a friend but this will not generate a link because of mutual consent. In general, with the Myerson game, there are many equilibria, which reduces the attractiveness of this approach.

A solution to this problem has been proposed by Jackson and Wolinsky (1996). In their seminal paper, they introduce an alternative solution concept for network formation games, namely, pairwise stability, which provides a network equilibrium notion. Let us define it.

Consider some payoff function $u(\mathbf{g}) = (u_1(\mathbf{g}), \ldots, u_n(\mathbf{g}))$ that assigns a payoff to every agent in N as a function of the underlying network $\mathbf{g}$ connecting them.

Definition 2: A network $\mathbf{g}$ is pairwise stable for the payoff function u if and only if

1. for all $ij \in \mathbf{g}$, $u_i(\mathbf{g}) \geq u_i(\mathbf{g} - ij)$ and $u_j(\mathbf{g}) \geq u_j(\mathbf{g} - ij)$
2. for all $ij \notin \mathbf{g}$, if $u_i(\mathbf{g}) < u_i(\mathbf{g} + ij)$, then $u_j(\mathbf{g}) > u_j(\mathbf{g} + ij)$

In other words, a network is pairwise stable if (1) no player gains by cutting an existing link, and (2) no two players not yet connected both gain by creating a direct link with each other. Pairwise stability thus only checks for one-link deviations. (This weak equilibrium concept is often interpreted as a necessary condition for stronger stability concepts.) It requires that any mutually beneficial link be formed at equilibrium but does not allow for multilink severance. (There are other network equilibrium concepts, which are often refinements from the pairwise-stability equilibrium notion. See Bloch and Jackson (2006) for a complete overview on this issue. In particular, they compare variations on three types of definitions: those based on a pairwise-stability notion, those based on the Nash equilibria of a link formation game, and those based on equilibria of a link formation game where transfers are possible.) This notion takes into account the individual incentives to create and sever links and the necessary mutual consent between both sides for a link to be formed. (Bala and Goyal (2000) extend the Myerson model described above by only considering directed networks, i.e., individuals form links unilaterally without requiring the consent of the other party to create a link.)

Pairwise-stable networks can be interpreted as the limiting graphs of a dynamic procedure of network formation. Suppose, indeed, that players myopically add or sever links to improve their current status, and that only one link is added or removed at a time. When this process converges, the networks ultimately reached are pairwise stable. (Note that network transitions only concern one link at time. The dynamics may thus lock in (the set of limiting graphs need not be unique) or cycle. See Jackson and Watts (2002) for more details.)

Let us now define strong efficiency.

Definition 3: A network $\mathbf{g}^E \subset \mathbf{g}^N$ is strongly efficient if

$$W(\mathbf{g}^E) \equiv \sum_{i \in \mathbf{g}^E} u_i(\mathbf{g}^E) \geq W(\mathbf{g}) \equiv \sum_{i \in \mathbf{g}} u_i(\mathbf{g}) \quad \text{for all } \mathbf{g} \subset \mathbf{g}^N$$

Observe that this concept of efficiency is utilitarian and not Paretian since this definition says that the socially efficient network is the one for which the sum of utilities of all agents is the highest among all possible networks with n agents.

A simple model: the connections model

Jackson and Wolinsky (1996) have proposed a simple model where the utility function of each individual i in a network $\mathbf{g}$ is given by

$$u_i(\mathbf{g}) = \sum_{j \neq i} \delta^{d(i,j)} - \sum_{j \in N_i(g)} c = \sum_{j \neq i} \delta^{d(i,j)} - d_i(\mathbf{g})c \qquad [5]$$

where $0 < \delta < 1$ gives the value of the link between two individuals i and j, $d(i,j)$ is the geodesic distance between i and j, i.e., the length of any shortest path between i and j, and finally c is the cost of forming a link. In this formulation, when individual i has a direct link with j, he/she first benefits from this link by obtaining δ (since, for any direct link, $d(i, j) = 1$) but then he/she may benefit from the direct links of j by obtaining $\delta^{d(i,j)}$ (indirect connections, which are weighted by a decay factor).

Observe that if two agents create a link between them it is never detrimental to a third party (positive externalities). This is because creating a new link does not affect the cost of a third player (he/she still has the same number of direct links) but can affect his/her gains since a new link can shorten the distance between a third player and another one. Here is an example (Figure 1) of utilities for the following star network.

We have the following result for the connections model (Jackson and Wolinsky, 1996):

Proposition 2: In the connections model in which the utility of each player $i = 1, \ldots, n$ is given by eqn [5], we have

1. A pairwise stable network has at most one (nonempty) component.
2. For $c < \delta - \delta^2$, the unique pairwise stable network is the complete graph g^N.
3. For $\delta - \delta^2 < c < \delta$ a star encompassing all players is pairwise stable, but not necessarily the unique pairwise stable graph.
4. For $\delta < c$, any pairwise stable network that is nonempty is such that each player has at least two links.

This proposition characterizes the pairwise-stable equilibria. In particular, it says that if $\delta - \delta^2 < c < \delta$, then the star-shaped is a pairwise stable equilibrium. Let us check if this is true for the network described in Figure 1. If the star agent, player 2, wants to delete a link (he/she cannot create any new link), his/her net utility is $c - \delta$. If $c < \delta$, this will never happen. If a peripheral agent (say player 1) deletes a link, his/her net utility is $c - \delta$ while if he/she creates a link (with player 3), his/her net utility is $\delta - c - \delta^2$. Any of these two actions will never take place if $\delta - \delta^2 < c < \delta$. It is easily verified that this same condition holds for a star-shaped network with n agents to be pairwise stable. As can be seen in this proposition, one of the main problems of pairwise-stable networks is that it is very difficult to provide a full characterization of the set of equilibrium networks. (It is indeed well known that noncooperative games of network formation with nominal lists of intended links are plagued by coordination problems (Myerson, 1991; Jackson, 2008). Cooperative-like stability concepts solve them partially, but heavy combinatorial costs still jeopardize a full characterization.)

Figure 1 Utility values in a star-shaped network.

Let us now give a result in terms of efficiency.

Proposition 3: The unique strongly efficient network in the symmetric connections model, where the utility of each player $i = 1,\ldots,n$ is given by eqn [5], is

1. the complete graph g^N if $c < \delta - \delta^2$.
2. a star encompassing all players if $\delta - \delta^2 < c < \delta + ((n-2)/2)\delta^2$
3. no links (the empty network) if $\delta + ((n-2)/2)\delta^2 < c$.

There is therefore a tension between stability and efficiency. Take part (4) of Propositions 2. In the high cost range ($c > \delta$), the only (nondegenerated) pairwise-stable networks are those that are overconnected from an efficiency perspective. For example, when $c > \delta$, the star cannot be pairwise stable but it is an efficient network.

A second model: the coauthor model

In this case, for $n_i > 0$ (it is assumed that for $n_i = 0$, $u_i(\mathbf{g}) = 0$), the utility function of a player $i = 1,\ldots, n$ in network $\mathbf{g}$ is given by

$$u_i(\mathbf{g}) = \sum_{j \in N_i(\mathbf{g})} \left[\frac{1}{d_i} + \frac{1}{d_j} + \frac{1}{d_i d_j}\right]$$

where $d_i \equiv d_i(\mathbf{g})$ is the number of direct links player i has (or equivalently the number of projects player i is involved in). Here, each player is a researcher and a link ij is a joint project (or joint paper or collaboration) between players i and j.

Each researcher has a fixed amount of time to spend on research and so the time each researcher i spends on a given project is inversely related to the number of project d_i he/she is involved in. The synergy between two researchers i and j are captured by the term $1/(d_i d_j)$. Here, the more projects each researcher is involved with, the lower the synergy that is obtained per project. There is no direct cost of forming a link but an indirect cost because of congestion.

Contrary to the connections model, when two agents create a link, it is never beneficial to a third party (negative externalities). This is because creating a new link does affect the time the researcher will spend on other projects with the researchers he/she is already connected to.

Proposition 4: In the coauthor model,

1. if n is even, then the strongly efficient network is a graph consisting of $n/2$ separate pairs (dyads), and
2. a pairwise-stable network can be partitioned into fully intraconnected components, each of which has a different number of members. If k is the number of members of one such component and k' is the next largest in size, then $k > (k')^2$.

Choosing Both Actions and Links

There are different models that have combined actions' and links' choices. For example, Bloch and Dutta (2009) proposed a model where both link intensities and network formation are modeled. For games with strategic substitutes, Galeotti and

Goyal (2010) have developed a static model where players choose both actions and links while López-Pintado (2008) investigates a dynamic one. Because we have focused on games with strategic complements, we would like now to expose the static model of Cabrales et al. (2011). (See also Konig et al. (forthcoming) for a dynamic model of network formation with strategic complements in efforts.)

Consider a simultaneous move game of network formation (or social interactions) and investment. $N = \{1,\ldots, n\}$ is a finite set of players, and $T = \{1, \ldots, t\}$ is a finite set of types for these players. We let n be a multiple of t, i.e., $n = mt$ for some integer $m \geq 1$, so that there is the same number of players of each type. The case $n = t$ is referred to as the baseline game and the general case $n = mt$ as the m–replica of this baseline game. For each player $i \in N$, we denote by $\tau(i) \in T$ his/her type. In an m–replica game, there are exactly m players of each type $\tau \in T$. This replica game allows us to take limits as the population becomes large without having to specify the types of the new individuals that are added.

Let $c > 0$. Player i's utility is equal to

$$u_i(\mathbf{x}, \mathbf{s}) = a_{\tau(i)}x_i + \phi \sum_{j=1, j\neq i}^{n} g_{ij}(\mathbf{s})x_i x_j - \frac{1}{2}cx_i^2 - \frac{1}{2}s_i^2 \qquad [6]$$

where $x_i \geq 0$ is the productive effort taken by player i, with $\mathbf{x} = (x_1,\ldots, x_n)$ being a profile of productive efforts while $s_i \geq 0$ is the socialization effort of player i, with $\mathbf{s} = (s_1,\ldots, s_n)$ being a profile of socialization efforts. This utility is very similar to the one defined in eqn [1] with the difference that the socialization effort s_i is also included. In eqn [6], the returns to the investment are the sum of a private component and a synergistic component. The private returns are heterogeneous across players and depend on their type. We denote by $\mathbf{a} = (a_1,\ldots, a_t)$ the profile of these private returns, where $0 < a_1 < a_2 < \ldots < a_t$. Payoffs have nonnegative cross effects, i.e.,

$$\frac{\partial^2 u_i(\mathbf{x}, \mathbf{s})}{\partial x_i \partial x_j} = \phi g_{ij}(\mathbf{s}), \quad \text{for all } i \neq j, \qquad [7]$$

reflecting strategic complementarities in productive investments ($\phi \geq 0$ corresponds to the level of synergistic returns). As in eqn [1], the size $\phi g_{ij}(\mathbf{s}) \geq 0$ of these complementarities depends on the profile of socialization efforts, and varies across different pairs of players.

The key innovation is $g_{ij}(\mathbf{s})$, which determines link formation. Players i and j interact with a link intensity given by

$$g_{ij}(\mathbf{s}) = \frac{s_i s_j}{\sum_{j=1}^{n} s_j} \qquad [8]$$

By definition, links are symmetric, i.e., $g_{ij} = g_{ji}$. We also allow for self-loops (when $i = j$). From eqn [8], we can determine the adjacency matrix $\mathbf{G}$ of this network where each cell ij is $0 < g_{ij} < 1$.

A key innovation of this article is that the synergistic effort $\mathbf{s}$ is generic within a community – a scalar decision. Socializing is not equivalent to elaborating a nominal list of intended relationships, as in the literature on network formation surveyed by Jackson (2008) and exposed above. We have seen (see Proposition 2) that this leads to too many equilibria and that it is very difficult to provide a full characterization of the set of equilibrium networks. To avoid this problem, here, network formation is not the result of an earmarked socialization process so that agents put efforts in socialization that may result in links between agents. This choice of a model without earmarked socialization greatly improves the tractability of the analysis. Unlike with richer models of link formation a la Jackson and Wolinsky (1996), we can resort to off-the-shelf Nash equilibrium analysis without being burdened by the extreme (combinatorial) multiplicity problems of the other models. As a result, the authors can perform a standard type of equilibrium analysis that equates marginal costs and benefits of both production and socialization. Define:

$$\Phi(\mathbf{a}) = \phi \frac{\sum_{\tau=1}^{t} a_\tau^2}{\sum_{\tau=1}^{t} a_\tau}. \qquad [9]$$

Cabrales et al. (2011) demonstrate the following result.

Proposition 5: Suppose that $2\,(c/3)^{3/2} > \Phi(\mathbf{a}) > 0$. Then, there exists an m^* such that for all m–replica games with $m \geq m^*$, there are exactly two stable interior pure strategy Nash equilibria. These pure strategy Nash equilibria are such that, for all players i of type τ, the strategies (s_i, x_i) converge to $(s^*_{\tau(i)}, x^*_{\tau(i)})$ as m goes to infinity, where $s^*_{\tau(i)} = a_{\tau(i)}s$, $x^*_{\tau(i)} = a_{\tau(i)}x$, and (s, x) are positive solutions to

$$\begin{cases} s = \Phi(\mathbf{a})x^2 \\ x[c - \Phi(\mathbf{a})s] = 1 \end{cases} \qquad [10]$$

In other words, when $\Phi(\mathbf{a})$ is small enough compared to the inframarginal cost for a productive investment, the system of eqn [10] with two unknowns has exactly two positive solutions. As m gets large, each such solution gets arbitrarily close to a pure strategy Nash equilibrium of the corresponding m–replica game. We get two approximate Nash equilibria. Besides, as m gets large, every pure strategy Nash equilibrium gets arbitrarily close to a solution of eqn [10]. The equilibrium multiplicity identified in Proposition 5 reflects an intertwinned coordination problem in the socialization process and in the production technology.

The authors are then able to compare the actions and payoffs of players across the two approximate equilibria characterized in Proposition 5. They show that the equilibrium actions can be ranked component-wisely and the equilibrium payoffs can be Pareto-ranked accordingly. There is a Pareto-superior approximate equilibrium $(\mathbf{s}^*, \mathbf{x}^*)$ and a Pareto-inferior approximate equilibrium $(\mathbf{s}^{**}, \mathbf{x}^{**})$ while the socially efficient outcome lies in between the two equilibria. Formally, $(\mathbf{s}^*, \mathbf{x}^*) \geq (\mathbf{s}^E, \mathbf{x}^E) \geq (\mathbf{s}^{**}, \mathbf{x}^{**})$ and $\mathbf{u}(\mathbf{s}^E, \mathbf{x}^E) \geq \mathbf{u}(\mathbf{s}^*, \mathbf{x}^*) \geq \mathbf{u}(\mathbf{s}^{**}, \mathbf{x}^{**})$, where $\geq$ is the component-wise ordering. This simple model has shown how the set of equilibria can be reduced and equilibria can be characterized when agents do not direct their links but instead choose some effort in socialization.

Networks in Economics: Applications and Empirical Aspects

We would like now to study two important applications of economic networks: labor market and crime networks.

Labor-market Networks

There is a host of evidence showing that social networks are pervasive in the labor market. For instance, Holzer (1987, 1988) documents that, in the United States, among 16- to 23-year-old workers who reported job acceptance, 66% use informal search channels while only 11% use state agencies and 10% newspapers. (See also Granovetter (1995) for additional evidence.) Topa (2001) argues that the observed spatial distribution of unemployment in Chicago is consistent with a model of local interactions and information spillovers, and may thus be generated by an agent's reliance in informal methods of job search such as networks of personal contacts. Similarly, Bayer et al. (2008) document that people who live close to each other, defined as being in the same census block, tend to work together, i.e., in the same census block. (For a survey of the literature on social interactions and the labor market, see Ioannides and Loury (2004).) Let us now provide a simple model that captures these facts.

The model

Let us describe the model of Calvó-Armengol and Jackson (2004). Time evolves in discrete periods indexed by t. The vector σ_t describes the employment status of the workers at time t. If individual i is employed at the end of period t, then $\sigma_{it} = 1$ and if i is unemployed then $\sigma_{it} = 0$.

A period t begins with some agents being employed and others not, as described by the vector $\boldsymbol{\sigma}_{t-1} = (\sigma_{1t-1},\ldots,\sigma_{nt-1})$ that gives the employment status of all workers from the last period. Next, information about job openings arrives. In particular, any given individual hears about a job opening with probability γ i.e. between 0 and 1. This job arrival process is independent across individuals. If the individual is unemployed, then he/she will take the job. However, if the individual is already employed then he/she will pass the information along to a friend, picked at random among unemployed friends. As stated above, the graph or network $\mathbf{g}$ summarizes the links of all agents, where $g_{ij} = 1$ indicates that i and j know each other (strong tie), and share their knowledge about job information, while $g_{ij} = 0$ indicates that they do not know each other. Finally, the last thing that happens in a period is that some agents lose their jobs. This happens randomly according to an exogenous breakup rate, δ, which is between 0 and 1. We are able to write the probability $\mathbb{P}_{ij}$ of the joint event that individual learns about a job and this job ends up in individual j's hands. It is equal to

$$\mathbb{P}_{ij}(\boldsymbol{\sigma}) = \begin{cases} \gamma & \text{if} \quad \sigma_i = 0 \text{ and } i = j \\ \gamma / \sum_{k:\sigma_k=0} g_{ik} & \text{if} \quad \sigma_i = 1,\ \sigma_j = 0, \text{ and } g_{ij} = 1 \\ 0 & \text{otherwise} \end{cases} \qquad [11]$$

where the vector σ describes the employment status of all the individuals at the beginning of the period. In eqn [11], γ is the probability of obtaining a job information without using friends and relatives. Three cases may then arise. If individuals i and j are unemployed ($\sigma_i = \sigma_j = 0$), then the probability that j will obtain a job is just γ since individual i will never transmit any information to j. If individual i is already employed and his/her friend j is not ($\sigma_i = 1$, $\sigma_j = 0$), then individual i transmits this job information to all his/her direct unemployed neighbors, whose total number is $\sum_{k:\sigma_k=0} g_{ik}$. We assume that all unemployed neighbors are treated on equal footing, meaning that the employed worker who has the job information does not favor any of his/her direct neighbors. As a result, the probability that an unemployed worker j is selected among the $\sum_{k:\sigma_k=0} g_{ik}$ unemployed direct neighbors of an employed worker j is given by $\gamma / \sum_{k:\sigma_k=0} g_{ik}$. Finally, if individual j is employed, then he/she does not need any job information, at least in the current period.

The first result obtained by Calvó-Armengol and Jackson (2004) is the following.

Proposition 6: The higher $d_i(\mathbf{g})$, the number of strong ties (direct friends) individual i has, the higher is his/her individual probability of finding a job.

Indeed, if an individual has more strong ties (direct friends), then he/she is more likely to hear on average about more jobs through them but his/her chance of finding a job directly does not increase since γ is not affected by the size of the network. This result is quite intuitive since, when the number of direct connections increases, the source of information about jobs is larger and people find it easier to obtain a job through their friends and relatives. This is the first prediction of this model, which implies that, the greater chance workers have of finding a job, the higher is the number of their strong ties. Observe that the individual probability of finding a job through strong ties for individual j is obviously not given by eqn [11] since $\mathbb{P}_{ij}(\mathbf{s})$ is the probability that only one individual, i, who hold a strong tie with j, and who is aware of some job, will transmit this information to individual j. To determine the individual probability of obtaining a job for j, one has to do the calculation for all the direct friends of i.

We would now like to study the impact of weak ties (indirect friends or path-connected friends) on the individual probability of finding a job. Calvó-Armengol and Jackson (2004) show that, in steady state, there is a positive correlation in employment status between two path-connected workers. This result is not at all easy to obtain since, in the short run, the correlation is negative. Indeed, in a static model, if an employed worker is directly linked to two unemployed workers, then if he/she is aware of a job, he/she will share this job information with two unemployed friends (see eqn [11]). These two persons, who are path connected (path of length two), are thus in competition and one (randomly chosen) will obtain the job and be employed while the other will stay unemployed. So their employment statuses will be negatively correlated (see Calvó-Armengol, 2004).

Let us now give the intuition why this negative correlation result does not hold in a dynamic labor-market model. Consider the star-shaped network described in Figure 2 with three individuals, i.e., $n = 3$ and $g_{12} = g_{23} = 1$. Suppose the employment status of these three workers from the end of the last period is $\sigma_{t-1} = (0,1,0)$. In the figure, a black node represents an employed worker (individual 2), while unemployed workers (1 and 3) are represented by white nodes. Conditional

Figure 2 Employment correlations in a star-shaped network.

on this state $\boldsymbol{\sigma}_{t-1}$, the employment states σ_{1t} and σ_{3t} are negatively correlated. As stated above, this is due to the fact that individuals 1 and 3 are 'competitors' for any job information that is first heard by individual 2.

Despite this negative (conditional) correlation in the short run, individual 1 can benefit from individual 3's presence in the longer run. Indeed, individual 3's presence helps improve individual 2's employment status. Also, when individual 3 is employed, individual 1 is more likely to hear about any job that individual 2 hears about. These two aspects counter the local (conditional) negative correlation, and help induce a positive correlation between the employment status of individuals 1 and 3.

Proposition 7: Under fine enough subdivisions of periods, the unique steady-state long-run distribution on employment is such that the employment statuses of any path-connected agents are positively correlated.

The proposition shows that, despite the short-run conditional negative correlation between the employment of competitors for jobs and information, in the longer run any interconnected workers' employment is positively correlated. This implies that there is a clustering of agents by employment status, and employed workers tend to be connected with employed workers, and vice versa. The intuition is clear; conditional on knowing that some set of agents are employed, it is more likely that their neighbors will end up receiving information about jobs, and so on. The benefits from having other agents in the network outweigh the local negative correlation effects, if we take a long-run perspective.

Proposition 8: The longer the length of two-path connected individuals (i.e., weak ties), the lower is the correlation in employment statuses between these two individuals.

Indeed, the correlation between two agents' employment is (weakly) decreasing in the number of links that each an agent has, and the correlation between agents' employment is higher for direct compared to indirect connections. The decrease as a function of the number of links is due to the decreased importance of any single link if an agent has many links. The difference between direct and indirect connections in terms of correlation is due to the fact that direct connections provide information, while indirect connections only help by indirect provision of information that keeps friends, friends of friends, etc., employed. In other words, the longer the path in the social network between two individuals, the weaker is the effect of job transmission.

Empirical test

Using individual-level data from the UK Labour Force Survey, Patacchini and Zenou (2012a) test this model by looking at the employment prospects of ethnic minorities. To the traditional determinants of employment rates (sex, age, education, years since arrival in the United Kingdom, percentage of high-skilled leaving nearby, etc.), they add the local ethnic employment density bands based on travel time between areas.

Because they do not have direct data on social networks, Patacchini and Zenou (2012a) conjecture that the social space is highly correlated to the physical space for ethnic minorities in relatively small areas. This approximation is based on the fact that, in relatively small areas, ethnic minorities of a given group (say Indians or Pakistanis) are likely to interact with other ethnic minorities from the same group and thus exchange information about jobs. In other words, ethnic employment density is interpreted as a proxy for the strength of social contacts in delivering information about jobs.

Patacchini and Zenou (2012a) test Propositions 6 and 8 described above, which show that the individual probability of finding a job increases with the number of strong ties and weak ties, and the longer the length of weak ties, the lower is this probability.

They find that the higher is the percentage of employed workers from a given ethnic group living nearby, the higher is the probability of finding a job through social networks (Proposition 6). This effect decays, however, very rapidly with distance, losing significance beyond approximately an hour travel time (Proposition 8). They argue that local social interactions between people of the same ethnicity can explain this positive relationship and its spatial trend.

Let us now investigate our second application: criminal networks.

Criminal Networks

It is well established that delinquency is, to some extent, a group phenomenon, and the source of crime and delinquency is located in the intimate social networks of individuals (see, e.g., Sutherland, 1947; Sarnecki, 2001; Warr, 2002). Indeed, delinquents often have friends who have themselves committed several offenses, and social ties among delinquents are seen as a means whereby individuals exert an influence over one another to commit crimes.

A simple model

Glaeser et al. (1996) were among the first to model criminal social interactions. In their model, criminal interconnections act as a social multiplier on aggregate crime. They impose, however, a specific network structure, the circle, for the location of criminals. Following Calvó-Armengol and Zenou (2004) and Ballester et al. (2010), we would like to propose a more general model that can encompass any social network. For that, we will use the model described above by reinterpreting it in terms of criminal activities.

Denote by x_i the delinquency effort level (i.e., how often they commit crime) of delinquent i, and by $\mathbf{x} = (x_1, \ldots, x_n)^{\mathrm{T}}$ the population delinquency profile. Delinquents in network $\mathbf{g}$ decide how much effort to exert. Each agent i selects an effort $x_i \geq 0$, and obtains a payoff $u_i(\mathbf{x}, \mathbf{g})$ that depends on the effort profile $\mathbf{x}$ and on the underlying network $\mathbf{g}$, in the following way:

$$u_i(\mathbf{x}, \mathbf{g}) = \underbrace{\alpha x_i}_{\text{Proceeds}} - \underbrace{\frac{1}{2} x_i^2}_{\text{Cost of crime}} - \underbrace{p \cdot f \cdot x_i}_{\text{Cost of being caught}} + \underbrace{\phi \sum_{j=1}^{n} g_{ij} x_i x_j}_{\text{Positive peer effects}} \qquad [12]$$

where $\phi > 0$. This utility has a standard cost/benefit structure (as in Becker, 1968). The proceeds from crime are given by αx_i and are increasing in own effort x_i. The costs of committing

crime are captured by the probability of being caught $0 < p < 1$ times the fine fx_i, which increases with own effort x_i, as the severity of the punishment increases with one's involvement in crime. Individuals have a moral cost of committing crime equal to $(1/2)x_i^2$, which is also increasing in own crime effort x_i. Finally, the new element in this utility function is the last term $\phi \sum_{j=1}^{n} g_{ij}x_ix_j$, which reflects the influence of friends' behavior on own action. Denote $a \equiv \alpha - pf > 0$. Then eqn [12] can be written as

$$u_i(\mathbf{x}, \mathbf{g}) = ax_i - \frac{1}{2}x_i^2 + \phi \sum_{j=1}^{n} g_{ij}x_ix_j \qquad [13]$$

which is exactly the same as eqn [1]. We can thus apply Proposition 1 and show that, if $\phi\mu_1(\mathbf{g}) < 1$, there exists a unique Nash equilibrium in crime effort given by

$$\mathbf{x}^* = a(\mathbf{I} - \phi\mathbf{G})^{-1}\mathbf{1} = a\mathbf{b}(\mathbf{g}, \phi)$$

Policy implications

One interesting aspect of criminal networks is that we can propose alternative policies than those advocated by Becker (1968) and others. In particular, because of the network aspect, we can implement a key player policy, which consists in finding and getting rid of the key player, i.e., the delinquent who, once removed, leads to the highest aggregate delinquency reduction.

Given that delinquent removal has both a direct and an indirect effect on the group outcome, the choice of the key player results from a compromise between both effects. In particular, the key player need not necessarily be the one exerting the highest delinquency effort or, equivalently, the one with the highest Katz–Bonacich centrality measure. The planner's objective is thus to generate the highest possible reduction in aggregate delinquency level by picking the appropriate delinquent. Formally, the planner's problem is the following:

$$\max\left\{x^*(\mathbf{g}) - x^*\left(\mathbf{g}^{[-i]}\right) | i = 1, \ldots, n\right\},$$

where $x^*(\mathbf{g}) = \sum_i x_i^*(\mathbf{g})$ is the total equilibrium level of crime in network $\mathbf{g}$ and $\mathbf{g}^{[-i]}$ is i the network when individual i has been removed. In terms of adjacency matrix, network $\mathbf{g}^{[-i]}$ corresponds to the adjacency matrix $\mathbf{G}^{[-i]}$, which is equal to $\mathbf{G}$ for which the row and column of individual i has been removed. The program above is equivalent to

$$\min\left\{x^*\left(\mathbf{g}^{[-i]}\right) | i = 1, \ldots, n\right\} \qquad [14]$$

From Ballester et al. (2006, 2010), we now define a new network centrality measure of player i, the intercentrality index, which solves this program.

$$c_i(\mathbf{g}, \phi) = \frac{b_i(\mathbf{g}, \phi)^2}{m_{ii}(\mathbf{g}, \phi)} \qquad [15]$$

where $m_{ii}(\mathbf{g}, \phi)$ is the ith element on the diagonal of $\mathbf{M} = (\mathbf{I} - \phi\mathbf{G})$. The Katz–Bonacich centrality of player i counts the number of paths in $\mathbf{g}$ stemming from i; the intercentrality counts the total number of such paths that hit i. It is the sum of i's Katz–Bonacich centrality and i's contribution to every other player's Katz–Bonacich centrality. Holding $b_i(\mathbf{g}, \phi)$ fixed, $c_i(\mathbf{g}, \phi)$ decreases with the proportion of i's Katz–Bonacich centrality due to self-loops, $m_{ii}(\mathbf{g}, \phi)/b_i(\mathbf{g}, \phi)$.

Let us now provide an example showing that the key player is not always the most active delinquent in a network.

Example: Consider the following network $\mathbf{g}$ (Figure 3).

We distinguish three different types of equivalent actors in this network, which are the following:

Type	*Players*
1	1
2	2, 6, 7, and 11
3	3, 4, 5, 8, 9, and 10

For $a = 1$, the following table computes for the network described in Figure 3 the value of delinquency efforts x_i, centrality measures $b_i(\mathbf{g}, \phi)$, and intercentrality measures $c_i(\mathbf{g}, \phi)$ for two different values of ϕ, 0.1 and 0.2. In each column, a variable with a star identifies the highest value.

ϕ	*0.1*			*0.2*		
Player type	x_i	$b_i(\mathbf{g},\phi)$	$c_i(\mathbf{g},\phi)$	x_i	$b_i(\mathbf{g},\phi)$	$c_i(\mathbf{g},\phi)$
1	0.077	1.75	2.92	0.072	8.33	41.67*
2	0.082*	1.88*	3.28*	0.079*	9.17*	40.33
3	0.075	1.72	2.79	0.067	7.78	32.67

First, note that type 2 delinquents always display the highest Bonacich centrality measure. These delinquents have the highest number of direct connections. Besides, they are directly connected to the bridge delinquent 1, which gives them access to a very wide and diversified span of indirect connections. For low values of ϕ, the direct effect on delinquency reduction prevails, and type 2 delinquents are the key players – those with the highest intercentrality measure d_i. When ϕ is higher, however, the most active delinquents are not anymore the key players. Now, indirect effects matter a lot, and eliminating delinquent 1 has the highest joint direct and indirect effects on aggregate delinquency reduction. Note that the network $\mathbf{g}^{[-1]}$ has 20 different links, while $\mathbf{g}^{[-2]}$ has 19 links. In fact, when ϕ is small enough, the key player problem minimizes the number of remaining links in a network, which explains why type 2 delinquents are the key player when $\phi = 0.1$ in this example.

Empirical test

Testing the idea of key players in crime is quite complicated since we need very detailed information about networks and crime outcomes. Fortunately, there is a unique database on

Figure 3 Network with 11 delinquents.

friendship networks from the National Longitudinal Survey of Adolescent Health (AddHealth). (The AddHealth Web site http://www.cpc.unc.edu/projects/addhealth describes survey design and data in details.) It collects data on students in grades 7–12 from a nationally representative sample of roughly 130 private and public schools in years 1994–95. In terms of networks, the most interesting aspect of the AddHealth data is the information on friendships. Indeed, the friendship information is based upon actual friends' nominations. Pupils were asked to identify their best friends from a school roster (up to five males and five females). As a result, $g_{ij} = 1$ if either i or j or both have nominated each other. Otherwise, $g_{ij} = 0$.

Using this dataset, Liu et al. (2011) try to identify key players for juvenile crime in the United States. First, as in the example above, they find that a little bit more than 20% key players are not the most active delinquents. This is because they have a crucial position in the network in terms of betweenness centrality. They also find that, compared to other criminals, 'key' criminals are less likely to be a female, are less religious, belong to families whose parents are less educated, and have the perception of being socially more excluded. They also feel that their parents care less about them, are less likely to come from families where both parents are married, and have more trouble getting along with teachers. An interesting feature is that key players are more intelligent (i.e., higher mathematics scores) than the average criminal and are more likely to have friends who are older (i.e., in higher grades), more religious and whose parents are more educated. Also, even though key players themselves do not have a better self-esteem, they are not more physically developed nor are they more likely to be urbanites than other criminals; their friends are.

The authors also try to determine how efficient a key-player policy as opposed to a random-player policy is, i.e., a policy that removes a criminal at random from the network. Figure 4 displays the results.

To plot this figure, Liu et al. (2011) put together networks of the same size and the average crime reduction for this size of networks under two policies. For example, for all networks of size 4 (horizontal axis), the average crime reduction is 29.94% when the key-player policy (vertical axis blue curve) is implemented while it is 23.86% when a random-target policy is implemented (vertical axis red curve). The difference in crime reduction between these two policies can be large, especially for big networks. This can justify why a key-player policy, although expensive, could be implemented.

Figure 4 Difference between a key-player policy and a random-target policy.

Concluding Remarks

The study of networks in economics is still at an early stage and much more research needs to be done. In this article, we have provided an overview on this literature by exposing its recent developments. We have seen that the models of network formation are often plagued by too many equilibria and that the full characterization of all possible equilibria is a very difficult task. On the contrary, the study of games on networks, where the network is fixed and the impact of the network structure on individuals' outcomes is analyzed, is much more developed since the existence, uniqueness, and characterization of equilibrium has been established. We have also seen how these models can easily be used to analyze issues related to labor and crime networks (and also education, R&D, cities, etc.; see Jackson and Zenou, forthcoming).

We believe that, in the future, more effort should be devoted to the formation of networks in a dynamic framework using some microfoundations based on economic choices. Indeed, following the physics literature, some economic models have been used to model dynamic network formation but links are usually formed in a random or probabilistic way. (In these models, usually, one agent at a time is selected to form or create links. This greatly simplifies the analysis and avoids the coordination problems highlighted above where all agents could delete or create links simultaneously.) Some recent papers have, however, tried to provide more microfounded models where links between agents are formed based on a careful cost and benefit analysis so that agents maximize their utility (see, in particular, Christakis et al., 2010; Mele, 2011; König et al., forthcoming).

We also believe that more work should be done to estimate empirically economic networks. We have shown how labor and crime networks could be estimated and what kind of policy implications they imply. Recent papers (Bramoullé et al., 2009; Calvó-Armnegol et al., 2009) have shown how econometric issues such as the reflection problem (Manski, 1993) and correlated effects can be solved using a network approach. This is a growing field (see, in particular, Patacchini and Zenou, 2012b; Banerjee et al., 2012) and we hope that many more tests on different economic aspects where networks are prevalent such as crime, microfinance, religion, smoking, teenage pregnancy, etc. will be performed in the future.

Abstract

Immense breadth and profound depth distinguish John von Neumann's contributions to mathematics. They range from the most abstract – for example, foundations of mathematics (axiomatization), through mathematical physics (quantum mechanics) to concrete applications in artificial intelligence and military technology. Together with economist Oscar Morgenstern, von Neumann laid the foundations of the theory of games, the powerful mathematical tool of contemporary economics. In particular, von Neumann was the first to prove the minimax theorem, on which the concept of rational strategy, fundamental in the theory of games, rests. Von Neumann may have stimulated the reductionist trend in the social sciences by his attempts to explain a wide range of psychological and social phenomena by considerations of self-interest; a psychology ascribed to *homo economicus*. Although von Neumann, and especially his followers, extended game theory to cooperative games, on which concepts associated with collective rationality (e.g., Pareto optimality) play a part, von Neumann did not appreciate the break-out of the theory of noncooperative games from the minimax paradigm, following the discovery of Prisoner's Dilemma and other noncooperative games in which the cardinal difference between individual and collective rationality is demonstrated.

John von Neumann was born Janos Neumann on 28 December 1903. He was the eldest son of Miksa (Max) Neumann and Margit (Margaret) Kann. The family prospered in the last decades before World War I. Max Neumann was a lawyer who was well known in banking circles, and he was later a banker. He was subsequently ennobled, hence the 'von' in John's name.

Max Neumann instilled his ardent love of high culture into his children. In the atmosphere in which John spent his childhood, his phenomenal precociousness in mathematics was soon discovered. His gymnasium teacher pointed out to John's father that there was no point in John's studying mathematics in school. Mature mathematicians were engaged as private tutors. His first paper, written jointly with one of them, appeared in 1922. John was recognized as a professional mathematician before he was 18.

After receiving his *matura*, von Neumann enrolled as a mathematics student in the University of Budapest. However, he did not attend classes and he only appeared at the end of each semester to take examinations. He was simultaneously enrolled first at the University of Berlin, Germany then in the *Eidgenossische Technische Hochschule* in Zurich, Switzerland. He received his doctorate in mathematics from the University of Budapest and the degree of *Diplomingenieur* in chemistry from the *Eidgenossische Technische Hochschule* almost simultaneously. The study of chemistry was probably motivated by the increasing importance of its applications in military technology. Toward the end of his life, von Neumann's most brilliant contributions were closely related to the development of weaponry.

Von Neumann's professional career falls roughly into three periods. He spent 5 years in Weimar, Germany (the period between the monarchy and the Third Reich) as *Privatdozent* in Berlin and Hamburg. Recognizing the impending Nazification of Germany, he accepted a visiting professorship at Princeton University and emigrated. Subsequently, he joined the newly founded Institute for Advanced Studies. The depression decade roughly marks the second period, when he made his most brilliant contributions to mathematics and to mathematical physics. In the last period, emphasis shifted to applied mathematics, particularly to aerodynamics and the physics of explosions and implosions, the development of nuclear weapons, and of electronic computers. His academic affiliation remained with the Institute of Advanced Studies. However, the locale of his most intense preoccupation was Washington, where his contributions to US military might were fully appreciated. On one of his last public appearances President Eisenhower presented him with the Medal of Freedom.

In Norman Macrae's biography of von Neumann (1992), the last chapter is aptly entitled 'With Astounding Influence.' The final scene is at the Walter Reed Hospital in Washington.

The great and important now flocked to his bedside. It was known that Johnny's illness might lead to his talking in his sleep, and Colonel Ford was told to place soldiers to ensure that he did not shout out military secrets. Von Neumann died on 8 February 1957.

An obituary by S. Ulam, a close friend and colleague, in the *Bulletin of the American Mathematical Society* lists titles of 125 publications and of 17 abstracts of papers presented to the American Mathematical Society (1958). The list ranges over all major fields of mathematics and some of physics, for example quantum theory and statistical mechanics. Von Neumann's doctoral dissertation was on axiomatization of mathematics based on set theory, a subject he taught at age 11- to 12-year-old future Nobel Laureate Eugene Wigner. This branch of mathematics seems to provide access to the way von Neumann viewed the functioning of the human mind at its best.

A prevalent view of mathematics (among non-mathematicians) is that mathematical concepts are essentially abstractions of experiences with the physical world. Von Neumann has on occasions expressed that view; and this seems strange, since his earliest dedication, manifested in his doctoral dissertation, was to the foundations (or axiomatization) of mathematics, which represents, perhaps more than any other branch, a complete break with concrete, sense-induced experiences. All universally recognized mathematical knowledge is gained from deduction alone, which is from chains of reasoning about what one assertion implies about another. Empirics plays no role whatsoever in this process.

David Hilbert, arguably the most outstanding mathematician of the nineteenth century, 'bequeathed' to mathematicians 23 problems to be solved in the course of the twentieth century. One of them was the 'axiomatization' of all mathematics, that is, a follow-up of Euclid's feat in geometry. This task appeared challenging, because of difficulties that arose in the highly original work of Georg Cantor on the arithmetic of so-called 'transfinite' numbers. It seemed as if paradoxes or, perhaps, even gross-contradictions appeared in that theory. The only way to clear them up was to axiomatize the entire realm of mathematics on the foundation of its most basic concept – that of a set, thus reducing all mathematical propositions to statements about relationships among sets.

Hilbert, who was markedly enthusiastic about Cantor's work, was convinced that such axiomatization could be accomplished. Other distinguished mathematicians, notably Hermann Weyl and L.E.J. Brouwer, thought it could not and recommended a revision of mathematics that would 'delegitimize' some of its most important branches (mostly dealing with continua). Von Neumann sided with Hilbert (who, in turn, recognized young von Neumann as a rising star) and undertook the task, which Bertrand Russell and Alfred North Whitehead had undertaken at the turn of the century and failed. Von Neumann also failed. In 1931 the problem was solved, if an impossibility proof can be regarded as a solution, by Kurt Gödel, who showed that any mathematical system of complexity comparable to that of elementary arithmetic or greater must contain propositions that cannot be shown to be either true or false. Yet it was von Neumann's unsuccessful effort to solve the problem bequeathed by Hilbert that in a way helped him lay the theoretical foundations of computer technology. He adopted Gödel's cataloguing of logical statements as numbers by cataloging computer instructions as numbers.

Von Neumann's preoccupation with the foundations of mathematics suggests that his philosophy of scientific cognition (it seems he recognized no other kind) was based on 'reductionism.' The merging of conceptual repertoires and methodologies of two disciplines, whereby one with fewer concepts absorbs the one with more, exemplifies reductionism. The best known example is the reduction of chemistry to physics. For example, the fundamental conceptual building blocks of classical chemistry were originally the elements. These differed qualitatively. Their combinations into compounds and, conversely, the break up of compounds into elements were the principal events constituting chemical processes. With the discovery of the periodic table and of the internal structure of atoms, the properties of elements were described in quantitative terms (e.g., numbers of electrons, protons, etc., characterizing the atoms of elements), and the basic events were explainable by physical laws. Thereby, much of chemistry was 'reduced' to physics, a more rigorous science. Eventually physiology was reduced to biochemistry, parts of psychology to physiology. In economics, reduction of macroeconomics (behavior of large economic systems) to microeconomics, that is, the behavior of *homo economicus* (a postulated 'atom' of economic activity) is in the spirit of reductionism.

Von Neumann's work in this spirit was particularly fruitful. For example, the conception of a human brain as a computer is certainly a reductionist step, since computer science is much more rigorous, that is, more mathematical than traditional cognitive psychology or the physiology of the nervous system. In general, the 'mathematization' of any discipline is in the spirit of reductionism. So it was with von Neumann's most important contribution to the social sciences, the discipline of which he undisputedly laid the foundation, namely, the theory of games.

Game theory can be clearly seen as a branch of decision theory in which more than one rational decision-maker (or 'actor') are involved. The prototypes of games examined in the theory comprise so-called 'games of strategy' such as chess, go, bridge, poker, etc., that is, contests in which facility in formal reasoning is decisive. Of special interest are 'two-person constant sum games,' in which the sum of the payoffs to the respective players is constant in all outcomes: the more one wins, the less the other wins or the more he loses. Hence, the interests of the two players are diametrically opposed.

It is in the spirit of reductionism that von Neumann built up the theory of economic behavior, on a foundation provided by the theory of the two-person constant sum game. In his treatment of so-called 'cooperative' n-person games ($n > 2$), some of the players may form a coalition and coordinate their strategies so as maximize their joint payoff. It is then in the interest of the remaining players to form their own coalition. If the n-person game is constant sum, then the game between the two coalitions is essentially a two-person constant sum game. If the sum is not constant, a 'dummy' player can be added whose winnings or losses in each outcome compensate for the differences, making the game constant sum. In this way, a theory of the 'cooperative' n-person game reduces to a game of completely opposed interests.

Von Neumann's great achievement was the proof of the so-called 'minimax theorem.' It asserts that every two-person constant sum game, in which a finite number of strategies are available to each player has a 'solution,' expressible as the outcome resulting from an independent choice by each player of a particular strategy, pure or mixed. A pure strategy is essentially an adoption of a plan to make a particular 'move' among those permitted by the rules in each of the possible situations that may occur in the course of the game. A mixed strategy is a probabilistic mixture of pure strategies. This concept was already introduced by E. Borel in 1921, but illustrated only in special cases. Von Neumann proved the general existence theorem in 1928. *Theory of Games and Economic Behavior*, coauthored with Oscar Morgenstern (1944) very soon attracted the attention of the American military establishment as a possible foundation of a mathematically precise rational conduct of conflict.

The minimax corresponds to what military strategists call the 'worst-case scenario,' the assumption that the enemy doesn't necessarily act so as to achieve the best possible outcome for himself but rather to impose the worst possible outcome on you. In situations analogous to the two-person constant sum game the two goals are identical, since confrontation of enemies is most naturally modeled by a constant sum game. The situation in so-called 'neoclassical' economics is similar. At the foundation of its reduction is theoretical framework is 'methodological individualism,' which P.H. Wicksteed (1933), perhaps to avoid the pejorative connotations of 'egoism,' called 'non-tuism' – the overriding goal of maximizing one's own payoff. As a result of impersonal

market forces (Adam Smith's 'invisible hand') an economic system so modeled is shown with mathematical rigor to tend toward an 'equilibrium,' assuming this to be the best attainable condition for everyone concerned. In this way, von Neumann's minimax theorem appeared to provide not only an idealized model of 'rationally conducted conflict,' but also a justification of a Hobbsian 'competition of every one with every one else.'

To the extent that some references are made in military doctrines to human behavior, these can be arguably included in the subject matter of the social sciences. Economics is unequivocally regarded as a branch of social science, indeed the most theoretically rigorous one. Thus, von Neumann's and Morgenstern's treatise can be justifiably celebrated as a most impressive contribution to social science. Paradoxically, an even more impressive contribution can be discerned in the pursuit of answers to questions that were not raised in the treatise but were inspired by it, namely, in the course of analyzing non-constant sum games.

As has been said, the US military establishments quickly recognized the potential of game theory in developing a 'science of rationally conducted conflict.' Generous support of further research was not long in forthcoming. Workers in the field were invited to the think tank established by the Rand Corporation. Attention was focused on experimental verification of theoretical predictions generated by game theory. Note that laboratory experimentation with a real economic system is practically impossible, while such experimentation on people playing specially designed games is easy, cheap, and, most importantly, reproducible.

The results of the early experiments with nonconstant sum games were disappointing. They in no way confirmed systematically the predictions of game theory based on the minimax principle. Neither did they systematically refute them in a way that would suggest a generalization of the theory to explain the discrepancy. However, a result was observed demonstrating a 'serendipity' effect – finding something more valuable than what was originally sought. Namely, a game was discovered that was soon called Prisoner's Dilemma, now a byword in the vocabularies of economics, social psychology, sociology, political science, management science, peace research, peace education, and philosophy. The game was discovered by M.M. Flood (1952) and M. Dresher and christened by A.W. Tucker, followers of von Neumann's leads. The name of the game stems from the following anecdote.

Two men are arrested on suspicion of burglary. There is not enough evidence to convict them unless at least one confesses. They can, however, be convicted of a lesser crime – possession of stolen goods, which carries a lighter sentence. If only one confesses, he is not prosecuted, while the other is given the most severe sentence. If both confess their sentence is reduced. If neither confesses, both get the lightest sentence (for the lesser crime). It turns out that it is in the interest of each to confess regardless of whether the other confesses or not. However, if both confess, both are given longer prison terms than if neither confesses.

The paradox brings out the distinction between individual and collective rationality. There are innumerable situations where this distinction is dramatically demonstrated. If a fire breaks out in a crowded theater, it is in every one's interest to get to an exit as quickly as possible. If all act 'rationally,' all may perish. It is in the interest of each fishing fleet to maximize its catch. If each acts 'rationally' there may soon be no fish to catch. It is in each of two hostile powers' interest to be stronger than the other is. An escalating arms race may lead to a disastrous war, which both wanted to avoid.

There is no indication that von Neumann was aware of the 'paradox of rationality' revealed by Prisoner's Dilemma, although the basic idea was expressed over a century before the publication of *Theory of Games and Economics Behavior* (1944) by von Neumann and Morgenstern. Having determined the equilibrium point of a market controlled by a duopoly, A.A. Cournot wrote in 1838:

> ... si les deux producteurs *s'etaient entendue* [emphasis in the original], la valeur de ... [price calculated on the basis of the agreement] aurait assigné à chacun un revenu plus grand que celui qu'ils obtiendront avec la valeur de ... [price determined by the duopolists independently]. Cournot, 1838

According to Merril Flood, who called von Neumann's attention to the paradox, the latter admitted that the Prisoner's Dilemma was a challenge to the minimax principle but did not take seriously the results of the Flood-Dresher experiment, which did not support the minimax (equilibrium) solution.

Two years after von Neumann's death, systematic experimentation with games similar to the Prisoner's Dilemma began in the USA and spread worldwide. It gave rise to a current contrary to that originating in the so-called 'rationality paradigm' which sought to reduce all aspects of human behavior to manifestations of self-interest and all 'rational' behavior to cost-benefit analysis. Von Neumann evidently thought within the framework of that paradigm. In his opinion, the fact that 40 000–50 000 annual traffic fatalities are tolerated in the USA indicates that this is an acceptable price to pay for the privilege of driving private automobiles. In the same spirit, he advocated acceleration of the arms race, on the grounds that if the Soviet Union got ahead, it would be more likely to launch a preventive nuclear strike against the USA. Apparently the opposite hypothesis (that the party behind might be more likely to launch a preventive war) did not occur to him.

How, then, can the suggestion be justified that the theory of games launched a movement in the social sciences transcending the reductionist model of the human condition? Recall the seemingly unassailable finality of the Newtonian paradigm resting on the metaphysics of a Euclidian three-dimensional space, independent flow of time, and an all-pervasive ether, defining an absolute system of coordinates. This paradigm was overthrown in the course of a few years by the relativity and quantum revolutions. The point is that the success of non-Newtonian physics was due to the clear axiomatization (except for implicit metaphysical postulates, such as independence of space and time) of the *Newtonian* paradigm. It was clear just what 'axioms' had to be dropped, generalized, or supplanted by others to account for phenomena inexplicable within the old paradigm. For example, the (implicit) postulate of an absolute system of coordinates was supplanted by the (explicit) postulate of the constancy of

the speed of light with respect to all systems of coordinates. In quantum mechanics, the independence of physical events from acts of observation (implicit in the Newtonian system) was supplanted explicitly by the Uncertainty Principle, incompatible with that assumption. Thus, the 'revolution' triggered by the Prisoner's Dilemma was fueled by the clear axiomatization of the rationality paradigm as manifested in von Neumann's and Morgenstern's theory of games. In particular, Pareto optimality (maximization of common rather than individual gain) supplanted the 'non-tuism' of neoclassical mathematical economics.

Also noteworthy is the 'reflexive' model of man developed by Vladimir Lefebvre (1998), in which the (implicit) assumption of 'non-tuism,' namely that the thought processes of interacting individuals are independent, is supplanted by a 'mirror image' assumption. An actor is assumed to be able to mentally reconstruct another actor's thoughts and feelings and, regarding him as his own 'mirror image,' acts accordingly. In the light of this model, the cooperative solution of the Prisoner's Dilemma and similar games is rigorously deduced.

In this way, Max Weber's conception of 'empathic (sic!) understanding' as an epistemological principle in the social sciences was revived. The dogma of 'value-free' social science was revealed as an analog of the Newtonian axiom of independence of observations from the act of observation. It appears that social science, no matter how rigorous, cannot be value free, because social self-observation plays a crucial part in its epistemology and inevitably generates value-oriented conclusions.

Neural Basis of Language Development

Abstract

The neural basis of language development is understood through studies of children with brain injuries and functional imaging of healthy children. Children with injuries to cortical areas that serve language in adults demonstrate that many different brain networks can support language development. However, children with injuries to cortex, white matter, or cerebellum may be deficient in multiple subdomains of language, indicative of the limits of plasticity and recovery. Healthy children show structural and functional lateralization for language processing in infancy. Increasing left lateralization occurs over development and is affected by age, language proficiency, and the nature of the task.

Introduction

The neural basis of language development is not fully understood. Evolving concepts about the neurobiology of adult language has influenced the experimental approaches and interpretations of findings about the neural basis of child language. Early studies in the child literature, as in the adult literature, inferred the neural basis of language from the neuropsychology of individuals with brain injuries. Recent research draws on structural and functional brain imaging in individuals with neural injuries and in children developing typically. Unanswered questions about the neural basis of language development await the further integration of multiple behavioral and imaging methodologies.

Neurobiological Basis of Mature Adult Language Functioning

Cortical Regions

The 'classical' theory of the neural basis of language emerged in the late nineteenth century based on clinical observations of adults with acquired brain injuries and aphasia. In that theory, the critical language substrate was localized to two distinct cortical regions in the left cerebral hemisphere and a white matter (a component of the nervous system comprised of the axons of cells, covered by myelin; insulates the axon and increases the rate of signal transduction; appears white, giving this brain compartment its name) tract running between them: (1) Wernicke's area (a region of the cortex of the brain that is located on the superior temporal gyrus on the left cerebrum near the junction of the temporal and parietal lobes, described as the posterior part of Brodmann area 22, and in conjunction with Broca's area, is implicated in language and speech processing), the posterior superior temporal area and supramarginal gyrus of the parietal lobe adjacent to the auditory cortex, was thought to be the neural substrate for speech perception and comprehension; (2) Broca's area (a region of the cortex of the brain that is located in the inferior frontal lobe, on the pars triangularis and pars opercularis, or Brodmann areas 45 and 44, and in conjunction with Wernicke's area, is implicated in language and speech production), the inferior frontal operculum, was thought to be the neural basis of speech production; and (3) the arcuate fasciculus, a white matter fiber tract coursing from posterior superior temporal to frontal lobe, was thought to be the main link for information flow within the system.

New experimental methods, including functional brain imaging that assesses the neural substrate of language in alive, awake, and processing individuals, has resulted in a 'contemporary' theory, distinct from its predecessor in several ways. First, classical brain areas are involved in various language functions: Wernicke's area has been implicated in phonological processing, interpretation of written words, and lexical (the vocabulary of a language) and semantic (the rules regulating the creation of meaning in a human language) aspects of language comprehension; Broca's area appears to be involved in syntactic processing, verbal short-term memory, and phonological processing. Second, adult language functioning uses a complex, interconnected, and overlapping set of networks, working in parallel in both hemispheres. A ventral stream that involves structures in the superior and middle portions of the temporal lobe appears to be involved in processing speech for recognition and comprehension (Hickok and Poeppel, 2007). A dorsal stream that involves structures in the posterior dorsalmost aspect of the temporal lobe and parietal operculum and posterior frontal lobe appears to be involved primarily in translating speech signals into articulatory representations for speech production (Hickok and Poeppel, 2007). However, these areas are also activated in individuals who are deaf and use sign language for communication, indicating that they are used in higher language processing as well as speech production (Petitto et al., 2000). Other networks come on line flexibly and dynamically, based on the modality of the inputs, top-down predictions from prior knowledge, linguistic and nonlinguistic context, task demands, such as comprehension versus judgments, and task difficulty (Price, 2010). Specific task requirements, such as suppressing unintended or irrelevant speech, may activate regions of the frontal lobe, anterior cingulate, and bilateral basal ganglia (Price, 2010).

The contemporary theory also shows that many but not all language functions show left lateralization. Prelinguistic auditory processing begins with bilateral activation and becomes left lateralized as speech processing begins (Price, 2010). Sentence-level comprehension results in activation of bilateral superior temporal sulci, whereas semantic retrieval

activates left angular gyrus and pars orbitalis. Left lateralization characterizes word retrieval, articulatory planning, motor cortex for initiation, and execution of speech (Price, 2010).

White Matter Pathways

White matter pathways link the various language networks. White matter pathways can now be dissected and analyzed using modern structural imaging techniques, such as diffusion tensor imaging (DTI, a magnetic resonance imaging method that uses the rate and direction of water diffusion to characterize the volume and properties of different compartments of the brain, and also the method of choice for visualizing and characterizing the white matter of the brain), a technique that differentiates white matter from cerebral spinal fluid and gray matter on the basis of differential water diffusion patterns in the three compartments (Basser et al., 1994). Asymmetries have been found in the volume of white matter pathways connecting the superior and middle temporal gyri to frontal lobes, suggesting that white matter shows left lateralization. Adult DTI data find that signals carried along the arcuate fasciculus and neighboring superior longitudinal fasiculus may be essential for semantic verbalization, syntactic comprehension, and skilled reading (Friederici, 2009). Another pathway, ventral to the arcuate, connects the superior temporal lobe to the inferior frontal lobe and is hypothesized to be important for language comprehension (Saur et al., 2008). The integrity of this ventral pathway may explain variations in language abilities and the degree of recovery after damage to the arcuate fasciculus.

Cerebellum

The cerebellum is also involved in language processing and organization. Two primary reciprocal pathways link the cerebellum to the frontal lobe via crossing fibers, such that the right cerebellum connects to left frontal lobe (Murdoch, 2010). These pathways coordinate linguistic ability with frontal lobe executive functions. Increased blood flow to the cerebellum, particularly the right cerebellum, occurs during complex language tasks, such as word generation and novel naming tasks, but not during simple language tasks (Murdoch, 2010). The left hemisphere of the cerebellum, though less active than the right has been shown to be involved in high-level linguistic skills, including sentence formulation, lexical-semantic operations, and organization and monitoring of responses in collaboration with the frontal lobes (Murdoch, 2010).

Findings from Neuropsychological Studies of Children's Language

Behavioral Studies of Children with Focal Injuries

Research on the neural basis of language development has focused on to what extent neural systems for language are organized prior to language learning. Before the modern era of neuroimaging, studies to address this question assessed language and cognitive function in children with early brain injuries. Children may suffer from strokes or other focal injury to the brain early in life. Children with vascular or other destructive lesions sometimes undergo a surgical procedure called hemispherectomy (the surgical procedure where one cerebral hemisphere is removed completely) that leaves them with a single functioning cortical hemisphere. These injuries and conditions can be conceptualized as naturalistic experiments that allow researchers to determine how the early injury affects the rate and pattern of language development and ultimately the status of mature language functioning (Feldman, 2005).

In early research on children with neural injuries, results were interpreted in terms of the 'nature–nurture' controversy. The 'nature' position argued that the brain is specialized for language based on genetic mechanisms. According to this view, injury to classical left hemisphere brain regions prior to language learning should result in severe delays and disabilities in language. The 'nurture' position argued that brain specialization results from environmental input and the experiences using language. In its extreme form, all cortical regions should be equally adequate to subserve language function, a position known as 'equipotentiality' (Lenneberg, 1967). According to this view, injury to classical left hemisphere brain regions prior to language learning should not seriously delay or disturb language learning because other regions and pathways could assume language functions. An intermediate position has been called 'developmental specialization.' It posits that particular brain regions have inherent anatomical, physiological, or computation predispositions for language learning and that if these regions are injured other areas may be able to serve language function. According to this position, predictions about the outcomes after focal injury are uncertain, depending upon multiple factors, including the degree and location of injury, the health of the remaining areas of cortex, and the internal structure of regions that assume language processing. The need to rely on pathways not usually associated with language may result in delays in development or deficits in mature language functioning (Feldman, 2005).

Children with focal injury to the left hemisphere at birth do not develop aphasia. Such children begin to speak in the toddler/preschool era (Feldman, 2005). By age 4 years, they master the complex morphosyntactic structures of language, even as complex as Hebrew (Levy et al., 1994). They outperform adults with similar injuries (Dick et al., 1999). These results demonstrate that the brain has impressive plasticity for language learning, and suggest that various brain regions can serve language function.

Children with focal injuries to either the left or the right hemisphere experience mild-to-moderate developmental delays in many language and cognitive functions compared to children without injury. Affected domains include prelinguistic skills, including the onset of babbling and communicative gestures, and linguistic skills, including the onset of vocabulary development, the use of word combinations, and the interpretation of syntactically complex sentences (Feldman, 2005). Their rate of developmental progress in vocabulary and sentence length in the preschool era once they begin to speak is comparable to children developing typically. However, they do not necessarily catch up to their peers. At school age, compared to children developing typically, they show conversational competence, and near average

scores on receptive vocabulary and syntax (the rules regulating sentence structure and organization in a particular language) (Demir et al., 2010). However, they show deficits in several areas: basic skills underlying language processing, such as speed of recognition and discrimination of sounds (MacWhinney et al., 2000); use of word order and animacy cues to determine the agent of the action in sentence comprehension (Feldman et al., 2002); interpretation of syntactically complex sentences (Dick et al., 1999); word learning, nonword repetition, and immediate serial recall (Gupta et al., 2003); and creation of narrative discourse (Demir et al., 2010). The maturity of language in children with focal injuries to either hemisphere is associated with features beyond lesion characteristics, including the presence of seizures and the quality of the parental input (Rowe et al., 2009). These findings indicate that plasticity after early brain injury is limited and that the integrity of networks in both hemispheres is important to child language. If any of the multiple pathways involved in language processing are damaged, the result is usually relative difficulties in language abilities, particularly with higher level of language processing skills.

It is still disputed whether children with left hemisphere focal injury have greater impairment in language skills than children with other lesions, including focal right hemisphere lesions. Studies of children with hemispherectomy for intractable epilepsy find that children with an isolated left and right hemisphere have similar potential for developing an adequate level of receptive vocabulary (Liegeois et al., 2008). Greater deficits after left than right hemisphere injury have been found in multiple studies, but the findings are restricted to specific ages, subdomains of language, and/or measures of language functioning. For example, before age 3 years, children with perinatal injury to left posterior brain regions were found to show greater delays in the development of expressive language skills than children with injuries in other locations (Thal et al., 1991) but this difference was no longer present at age 5 years (Vicari et al., 2000). Several studies of children with unilateral injury and with hemidecortication report that children with left hemisphere injury or an isolated right hemisphere have weaker skills than children with right hemisphere injury or an isolated left hemisphere in the domain of syntax, such difficulties comprehending sentences in which the only clue to meaning is syntactic structure (Dennis, 2009).

In children with injuries acquired after the early stages of language development, children with left hemisphere lesions, including left hemispherectomy have greater deficits than those with right hemisphere lesions. They show slower and less accurate understanding of syntactically difficult sentences in comparison to children with right hemisphere injuries of the same general type (Dennis, 2009). Those with lesions to the posterior left hemisphere have word finding difficulties and use semantic paraphasias and circumlocutions (Dennis, 2009). In a sample of children after hemispherectomy for epilepsy acquired on average at age 20 months, left hemisphere injury resulted in substantial language deficits, limitations in short-term verbal memory, and, to a lesser extent, in verbal intelligence (Liegeois et al., 2008). Such findings suggest that left lateralization of basic and complex language functions progresses after the initiation of language learning in the second year of life such that loss of the left hemisphere results in persistent language deficits. However, plasticity after a late destructive left hemisphere injury has been documented (Hertz-Pannier et al., 2002).

Children with a wide range of other central nervous system disorders, such as seizure disorder, traumatic brain injury, or tumor show deficits in language development (Dennis, 2009). Word finding difficulties are common in many different conditions, characterized by long pauses, creation of sequences that are not actual words (neologisms), circumlocutions, and excessive and inefficient productions (paraphasias). Children with traumatic brain injury in whom many brain pathways are injured show deficits in many aspects of language, from mastery of social functions of language (pragmatics) to accuracy of speech sounds (Campbell et al., 2007). These findings again suggest the importance of the integrity of the entire brain for competent language function.

Neuroimaging Studies of Children with Focal Injuries

Neuroimaging studies of children with early injuries provide additional insights into the neural organization of language development. Functional magnetic resonance imaging (fMRI – a magnetic resonance imaging method that directly measures changes in blood flow to brain areas to infer regions of brain activity during tasks or at rest) studies comparing children with focal left hemisphere injury to adults and typically developing children have found a rightward lateralization of language functions in those with injury. Activations in right hemisphere homologues of language areas during language tasks have been documented in children with early left middle cerebral artery stroke (Holland et al., 2007) and in a child with late left hemispherectomy (Hertz-Pannier et al., 2002). However, lateralization of language skills could not be reliably inferred from location of injury on an individual basis in children with epilepsy from early injury (Liegeois et al., 2004). Lesions in or near Broca's area were found to be more highly associated with peri-lesional activation within the damaged left hemisphere, whereas lesions remote from the classical language areas were more often associated with non-left language lateralization in several cases (Liegeois et al., 2004). In a study of children with early injury and their siblings, the level of both expressive and receptive language skills in children with early brain injuries correlated with the degree of activity in the left inferior frontal regions during a category fluency task, suggesting the relative advantage of left hemisphere networks for language function (Raja Beharelle et al., 2010). In addition, children with brain injury who showed bilateral activation in left and right superior temporal-inferior parietal regions had better language function than participants with either predominantly left- or right-sided unilateral activation.

Taken together, these findings support the interpretations from behavioral studies of the same population. Children with left hemisphere lesions activate nonclassical brain areas in language tasks, including regions of the right hemisphere. It is not yet clear whether the regions activated are those used in mature adult language functioning under other circumstances or whether these regions represent completely different networks. Predictions about which regions are activated after injury are difficult to make on the basis of lesion location or

size. However, activation of left hemisphere regions appears to confer an advantage to language function in children with early injuries.

Language Development after Injury to White Matter Pathways in Children

Neuropsychological studies also implicate the importance of white matter integrity in language development. Children born preterm, especially those born before 32 weeks gestation, are at high risk for injury to the white matter of the brain. DTI now reveals evidence of subtle white matter changes in a high proportion of children born preterm. Many studies document that performance on language assessments in this population remains below performance of well-matched controls (Barre et al., 2011; van Noort-van der Spek et al., 2012), even after controlling for intelligence quotient (Lee et al., 2011).

DTI studies in children born preterm confirm that the integrity of the white matter network affects language functioning. Multiple clusters on bilateral white matter tracts in both hemispheres were found to be associated with verbal IQ, linguistic processing speed, syntactic comprehension, receptive vocabulary, verbal memory, and reading in children born preterm (Feldman et al., 2012). The uncinate fasciculus connects the temporal lobes to the frontal lobes. Measures of both the left and right uncinate fasciculi have been found to correlate with receptive vocabulary (Mullen et al., 2011). The inferior frontal-occipital fasciculus runs from posterior occipital cortex through parietal and temporal cortex to the frontal lobe. The arcuate fasciculus connects the superior posterior temporal lobe and parietal lobe to the frontal lobe. Measures of the left and right arcuate fasciculi correlated with rapid naming scores in adolescents born preterm (Mullen et al., 2011). A recent case study identified a 12-year-old girl born preterm that was missing an arcuate fasciculus presumably from injuries associated with prematurity. This child nonetheless learned to speak and read. Further analysis of her white matter pathways found preserved ventral pathways (Yeatman et al., 2009). These findings suggest that alternative white matter pathways may support speech and reading, at least in selected cases. Finally, adolescents with evidence of injury to the corticospinal and corticobulbar pathways in the left hemisphere following preterm birth have been found to be at high risk for persistent difficulties in speech and oromotor control (Northam et al., 2012) though almost a third of the group did not have any such problems.

Language Characteristics after Cerebellar Injuries in Children

Children with surgical removal of cerebellar tumors in the right hemisphere show decreased verbal fluency, verbal intelligence, and syntax comprehension. Even 10 years after the surgery, such children often show speech deficits including consonant imprecision, reduced rate, and lack of variation in pitch and loudness. Poorer speech outcomes are more highly associated with right than left cerebellar tumors, implicating disruption of the reciprocal right cerebellar to left frontal pathways (Morgan et al., 2011). Cerebellar involvement in linguistic skills has also been shown in children born preterm. In this group, the cerebellum may be significantly reduced in volume and differentiation. Injuries in the cerebellum are associated with problems in language comprehension, expressive and receptive language, and syntax (Limperopoulos et al., 2007).

A syndrome called mutism with subsequent dysarthria has been described in children with severe lesions acquired later in development, such as Herpes simplex encephalitis and tumors of the posterior fossa. The total loss of speech is typically transient with subsequent speech characterized by slow rate, articulatory imprecision, and variable pitch. Though improvement over time is not uncommon, residual findings may be present a decade later (Dennis, 2009).

Genetic Abnormalities and Neural Basis of Language Development

The recent identification of a three-generation family in whom half of the members have a distinctive speech disorder and the other half of whom are entirely normal has opened a new chapter in the understanding of the connections of genes, neuroanatomy, neural function, and language (Vargha-Khadem et al., 2005). The autosomal-dominant speech disorder has been categorized as verbal dyspraxia; the affected and unaffected family members were found to differ primarily on the ability to repeat words, nonwords, and oral–facial movements. A genetic mutation in affected family members was localized to the FOXP2 gene on the long arm of chromosome 7. Detailed neuroanatomical studies of the brain have confirmed that the genetic mutation is associated reductions in the volume of the caudate nucleus, a subcortical gray matter structure within the basal ganglia that is typically associated with motor function. Other neuroanatomical findings include reductions in the volume of Broca's area, the precentral gyrus or motor strip, and the cerebellum. Affected family members showed less activation in Broca's area and more activation in posterior parietal and occipital regions during a language task than unaffected family members, linking the structural findings to abnormal function. The studies suggest that the development of fronto-striatal and fronto-cerebellar networks may be important for not only manual and motor sequences, but also speech motor control (Vargha-Khadem et al., 2005).

Neuroimaging in Typically Developing Infants and Children

Prelinguistic Language Processing in Infants

Modern neuroimaging has now opened the opportunity to study the neurobiology of language networks in intact, healthy, and typically developing infants and children, expanding understanding of the neural basis of language. fMRI and event-related potentials (ERPs – a measurement of the electrophysiological brain responses to a direct cognitive or sensory event) are the methods of choice for imaging healthy and typically developing infants and young children because they are noninvasive and avoid ionizing radiation.

Many behavioral studies document that human infants have impressive capacities to discriminate and categorize all of the phonetic distinctions within all human languages in early infancy, before they have acquired the ability to speak. Infants' phonemic representations can be modified without

training or implicit instruction based on the statistical distributions of speech input in order to converge to the phonemic categories of their primary language (Dehaene-Lambertz and Gliga, 2004). By the first birthday, children can no longer make distinctions between the speech sounds that are not part of their native language. This perceptual narrowing characterizes American Sign Language as well as verbal language (Kuhl and Rivera-Gaxiola, 2008). These abilities appear to involve general perceptual and cognitive abilities rather than language-specific abilities. To accomplish these abilities, infants appear to use the same neural structures as adults use in speech processing. fMRI and ERP studies find that an adult-like left-lateralized network of perisylvian areas become active when 3-month-old sleeping infants listen to sentences in their native language. The response was comparable for forward and backward speech stimuli, suggesting that the left hemisphere may be more responsive than the right to any auditory stimulus or to fast temporal auditory transitions characteristic of language rather than to language intonation (Dehaene-Lambertz et al., 2006). However, functional lateralization is not as strong in young children as it is in adults. Progressive neural commitment results in both the inability to detect nonnative phonetic contrasts and the concurrent ability to process larger language units, such as words and sentences. Using ERP, neural discrimination of phonetic contrasts at 7½ months of age correlated with language abilities at 2 and 2½ years of age (Kuhl and Rivera-Gaxiola, 2008).

Activations while listening to the mother's voice as opposed to other speech stimuli was modulated in several areas, including areas involved in emotional processing (amygdala, orbito-frontal cortex), and a large extent of the left posterior temporal lobe, suggesting that the mother's voice has a special status in the active engagement of posterior language areas. The fetus has the ability to hear its mother's voice more clearly than any other voice. These results suggest that early biological constraints on the language processing system interact with environmental inputs, particularly exposure to mother's voice, in the emergence of cortical networks for language processing in humans.

Broca's area activation during infancy can be found when stimuli are repeated, suggesting engagement of this region for verbal memory prior to any substantial verbalization. When a series of syllables change in either the characteristics of the voice (e.g., male to female) or the phonemes (e.g., /ba/ to /ga/), ERP studies find different scalp topographies and different latencies for the mismatch response. This finding suggests that, as in adults, different networks are involved in representations of different features of the stimulus (Dehaene-Lambertz et al., 2006). In addition, certain brain regions, such as the angular gyrus and precuneous, activate more during forward than backward speech, stimuli that vary primarily in intonation patterns rather than segmental features, suggesting sensitivity to prosodic patterns of the native language in the infant. Activation of the right dorsolateral prefrontal cortex in awake but not sleeping infants suggests that this region may be involved in active processes such as memory.

The development of white matter pathways in language-related temporal and frontal regions may be coincident with the development of vocabulary (Pujol et al., 2006). Rapid myelination of sensorimotor pathways begins almost immediately after birth, whereas rapid myelination of language-related pathways begins later at about 5 months of age. However, the rate of maturation was similar for temporal and frontal regions suggesting that the entire network acquires myelin simultaneously.

Functional Imaging in Toddlers and Preschoolers

Using ERP techniques on normal children learning language, a picture emerges that initial comprehension of language requires a wide and bilateral neural network. Progressive neural specialization and lateralization occurs in association with language experience rather than strictly with age. Specific ERP components in toddlers 13–20 months of age demonstrate differences between words that the child understands and words that are incomprehensible. Word comprehension shows both age and experience components on the ERP. At 13 months of age, the comprehension effects can be found over both the right and left hemispheres and over anterior and posterior regions. By 20 months of age, the effects are detectable only over the posterior left hemisphere. However, younger toddlers who are more advanced in language development show this laterality effect at a younger age than do less advanced children (Kuhl and Rivera-Gaxiola, 2008). In the toddler-preschool era phonological processing and word learning influence each other; children with strong phonetic skills learn vocabulary more quickly than children with weak phonetic skills and the more words children learn, the more they need to pay attention to phonetic units that distinguish one word from another (Kuhl and Rivera-Gaxiola, 2008). In terms of sentence processing, toddlers show adult-like components on ERP in response to syntactic and semantic errors but the differences in latency and scalp distributions of components differ compared to adults.

Functional Imaging in School-Aged Children and Adolescence

By the end of the preschool era, left lateralization can be identified on fMRI in many language functions: listening to speech versus backwards speech. Holland and colleagues completed a series of studies in which they used simple and complex syntactic and semantic tasks in children 5–18 years old (Holland et al., 2007). Simple tasks produced less activation than complex tasks. Syntactic tasks were less lateralized than semantic tasks. As children aged, the language tasks produced greater anterior change than posterior change. The greatest change in development was found in the verb generation task in which children generate as many verbs as possible for each noun presented (Holland et al., 2007). Comparisons of adult and school-aged children in reading single words out loud found that changes in left hemisphere activation patterns relate to both age and proficiency (Schlaggar et al., 2002). Thus, patterns of activation during language tasks continue to mature through childhood and into adulthood and are influenced by individual differences in skills as well as age.

White matter tracts within the language networks are late to mature. A DTI study that compared fiber tracts in adults and children found that dorsal pathways were less mature in school-aged children than in adults. This finding is consistent with functional imaging and behavioral data showing that

language functions remain relatively immature in school-aged children despite their impressive conversational abilities (Friederici, 2009).

Future Directions

Though much has been learned in the last decade about the neural basis of language development, many questions remain unanswered. How do abilities to perceive and categorize speech sounds lead to the production of speech? How do individual variations in anatomy of gray matter and white matter affect the development of language in individual children? How can we explain language impairments as features of other conditions or occurring in isolation?

As the field progresses, the usual taxonomy of language abilities into subdomains of phonology (the study of the organization and execution of sounds and phonemes in language and phonemes are the smallest unit of speech sounds that change the meaning of words), semantics, syntax, and pragmatics may need to be reconsidered in light of genetic and neurological studies. Performance factors, such as acoustic processing characteristics, motor planning, linguistic processing speed, and memory, may underlie apparent differences in language subdomains. Current methods of neuroimaging are well suited for the study of language in groups. However, vast individual differences are currently not well-understood using current methods. New methods under development that analyze structure and function in individuals will catapult the field. Future studies will also need to integrate multiple aspects of language functioning and multiple methods for understanding neural structure and function to broaden understanding about language as a complex and distinctly human function.

Neural Basis of Reading

Brigitte Stemmer, Université de Montréal, Montreal, QC, Canada

Published by Elsevier Ltd.

Abstract

Skilful reading is an astonishing accomplishment that implicates extracting sound and meaning from visual notations. This contribution investigates the neural substrates involved in reading and addresses questions such as whether there are neural systems in the brain dedicated to reading and whether reading affects brain organization in adults, in children learning to read, in the illiterate, and in the blind.

Introduction

In 1892, the neurologist J.J. Déjerine reported on a Parisian merchant who one morning woke up without being able to read a single word or letter despite being able to speak well and distinguish letters, objects, and persons around him (Déjerine, 1892 reported in Cohen, 2012). The patient was thus perfectly able to see and had all his cognitive capacities preserved but letters had become an abstract entity to which he could not assign any meaning. This story was taken as an indication that our brain possesses a system that is uniquely dedicated to reading. Since then researchers have tried to identify such a system or systems. In what follows, we will discuss the neural substrates that have been associated with sighted and non-sighted adult reading and with the process of learning to read in children, illiterate people, and the blind. Although most of this research has investigated alphabetical script languages there is a growing body of research that also looks at different script systems such as Chinese.

Neural Systems Involved in Adult Reading

One issue that has excited researchers is the observation that when reading scripts of languages as different as Japanese, Hebrew, or English, there is a small region in the brain that consistently becomes activated. This region has been called the visual word form area (VWFA) and lies within the left fusiform gyrus near the visual cortex in the occipital lobe (**Figure 1**). If this region is impaired, the patient may not be able to read anymore as was the case with Déjerine's patient. This was taken to support the notion that there are specific brain networks in the left occipital-temporal cortex (including the fusiform gyrus and the VWFA) dedicated to the reading process. However, as is frequently the case in research, what first seemed to be relatively clear-cut has turned out to be more complex. It has been found that the VWFA not only responds to written letters and words, but to all sorts of visual stimuli such as objects, faces, houses, and so on.

This observation has raised some controversy over the role of the VWFA and other regions activated during reading. While there is consensus that skilful reading requires the interaction of orthographic, phonological, and semantic processes, no consensus has been reached as to the neural substrates that underlie these processes (Cattinelli et al., 2013; Vogel et al., 2013). For example, one meta-analysis (that is a standardized analysis of a large amount of studies addressing a common topic) of 35 neuroimaging studies identified three neural network systems related to word and pseudoword reading (Cattinelli et al., 2013). One system, the *difficulty-modulated network*, was related to item difficulty and recruited brain regions in the left frontal region (Broca's region), the left superior parietal region, and the right cingulum. Broca's region was interpreted as contributing to translating orthographic representations into phonological ones, a process that is sensitive to item difficulty. The parietal and cingulum regions were thought to be related to attentional processes that are recruited, if stimuli are effortful. Another system, *the word-related network*, recruited left temporoparietal regions (including the fusiform gyrus). And a third system, the *pseudoword-related network*, comprised left and right parietal regions. These findings are in contrast to another meta-analysis based on five neuroimaging studies that did not identify distinct reading-related regions (Vogel et al., 2013). These researchers argued that the neural networks activated during word reading perform general processing. They *may* be used for reading but they are not used *predominantly for* and are *not specific to* reading (Vogel et al., 2013). The same meta-analysis also did not find neural regions for reading that *specifically* emerged with development. The question whether there are neural systems dedicated specifically to reading thus remains currently an open one. In addition, none of the meta-analytical approaches provide clear support for the classical models of reading such as the dual route model of reading or the connectionist single-mechanism account of reading.

Learning to Read

Being able to write and read what another person or you have written is a remarkable achievement. Despite different writing systems like Chinese or Japanese kanji, which depicts whole words, Japanese hiragana, which represents syllables, or English, which is an alphabetic system, we are able to acquire them all. Alphabetic writing systems rely on the fact that there is some correspondence between a letter (grapheme) and its sound (phoneme) (see **Figure 2**). In an ideal world, each phoneme would correspond to a single letter of the alphabet. Children learning to read would thus only have to learn the sonority that goes along with one letter. But unfortunately this is not the case, the correspondence between grapheme and phoneme is not always regular. Just consider the different

Figure 1 A vast brain circuit is active when people read or learn to read. As described in the text, the regions shown in red increase their activation and specialization during the acquisition of literacy. When readers become more skilled, activation decreases. In addition to these regions, there are also massive fiber bundles that link visual areas of the left hemisphere with areas in temporal brain regions. The figure is taken from Dehaene, S., 2013. Inside the Letterbox. How Literacy Transforms the Human Brain. Online publication: https://www.dana.org/Cerebrum/2013/Inside_the_Letterbox__How_Literacy_Transforms_the_Human_Brain/. The legend is phrased by Stemmer, B., based on Dehaene, 2013.

pronunciations of 'ou' in *soup*, *young*, or *thought*. Some languages like English are more irregular in this regard than others such as German or Italian.

Word-Level Reading

In order to be able to read, a child needs to consciously match the structures of the oral language with the visual code of the letters. This is not as simple as one may think. On the one hand, letters such as *e*, *o*, or *c* need to be distinguished as different letters although their form only differs minimally. On the other hand, letters such as 'A,' 'a,' or '*a*' need to be recognized as the same letters although their forms clearly differ. It has been suggested that reading acquisition partially recruits or 'recycles' preexisting cortical systems such as VWFA for novel tasks (such as reading) (Dehaene and Cohen, 2011). During the learning-to-read process, VWFA becomes more and more responsive to letters and letter sequences. fMRI studies have shown that activity in VWFA increases when orthographic strings (letters, words, and nonwords) become more familiar (**Figure 3**). Interestingly, the VWFA shows reduced activation in developmental dyslexia (*see* Dyslexia, Developmental). (For a summary, see Dehaene, 2011.) Growing expertise in reading is not only reflected in the modification of specific brain regions as shown by fMRI but also by the time course as reflected in EEG activity. When words or nonwords are presented on a screen, within 160–180 ms the brain registers this difference, which is reflected as a negative wave form in the EEG, the N170. The N170 does not show in illiterate children, but only after they have received instruction in reading (reported in Hruby and Goswami, 2011).

Figure 2 Different scripts and the relation of the written elements to their sounds. Some languages operate at the phoneme level (Italian, French), others at the syllable (Japanese hiragana) or whole word (Japanese kanji) level. Figure taken from Dehaene, S., 2011. Apprendre à lire. Odile Jacob, Paris. www.odilejacob.fr, p. 17.

Besides distinguishing and recognizing the form of letters and words, reading also entails developing efficiency in matching letters and the sound of language. It is thus not surprising that systematic correlations between visual and auditory brain areas and word decoding have been observed (Hruby and Goswami, 2011). One brain region that has been activated during these processes is the planum temporale, which is in close proximity to the primary auditory area. It has thus been suggested that this region is implicated in coding the sounds of a language.

Generally, word processing in children correlates with left-hemisphere activity. Increasing reading skills correlate with increasing neural activation in temporoparietal and occipito-temporal regions (see **Figure 1**). These correlations seem to depend on the developing visual expertise with letter strings

Figure 3 The upper part of the figure shows a sample stimulus from the Graphogame that was used to teach kindergarten children letter–speech sound associations. The brain of the children was investigated with fMRI before and after training (lower part of the figure). Increased activation in the visual word form area (VWFA) was seen in response to reading letters versus nonletters. Legend by Stemmer, B., based on McCandliss, B.D., 2010. Educational neuroscience: the early years. Proceedings of the National Academy of Sciences 107 (18), 8049–8050. Figure taken from McCandliss et al., 2010, which is based on work by Brem, S., et al., 2010. Brain sensitivity to print emerges when children learn letter–speech sound correspondences. Proceedings of the National Academy of Sciences 107 (17), 7939–7944.

such as words and developing skills in integrating letter and sound (Hruby and Goswami, 2011). The child learning to read alphabetic scripts needs to become aware that the spoken words of a language are made up of basic sounds (phonemes). Developing phonemic awareness in alphabetic language systems has been identified as a key stage in learning to read. In fact, language games that make the child manipulate syllables (e.g., rhyming games) have been shown to efficiently prepare the child for reading. Teaching a child to focus attention on letters and letter sequences that correspond to phonemes within the written word is essential. There is also some indication that systematically teaching grapheme–phoneme correspondence is more beneficial than teaching reading through global word forms without explicitly raising phoneme awareness. In fact, the latter strategy seems to activate inappropriate neural circuits in the right hemisphere and may hamper efficient learning (For a summary see Dehaene, 2011).

An interesting observation in children is that they frequently confuse letters that are mirror images of each other (such as *p* and *q* or *b* and *d*) when beginning to read. This has been related to the fact that the child's brain generally does not distinguish mirror images of an object and this difficulty is also reflected in distinguishing mirror letters.

Text-Level Reading

Most developmental reading studies focus on letter and word reading. However, reading is much more than reading words and implicates reading texts, comprehending syntactic structures, assigning meaning to and interpreting what has been read. Most generally, the language network is left lateralized by age four and overlaps largely with the network of older children and adults. Most differences are found with regard to higher order skills such as comprehension that continue to be fine-tuned. One of the few developmental studies comparing reading and listening comprehension of stories in children found that reading comprehension tasks activated a broader network in anterior frontal, temporal, and occipital (visual processing) regions (see Figure 4). These regions were also activated to a higher degree. This has been explained by different cognitive demands and strategies related to reading comprehension of stories. Further, the reading tasks activated more bilateral regions than the listening tasks although up to 25% of children had inconsistent laterality. When reading skills improve and phonological processing becomes more automatic, the magnitude of activation in posterior brain regions decreases.

Reading in Different Script Systems

We have already mentioned that different script systems follow different rules for assigning sounds to graphemes. An interesting question is thus whether different script systems implicate similar or different brain networks during reading. The answer is yes and no. Although reading procedures and the neural networks that underlie them are partly universal, the demands that alphabetic (e.g., English) and nonalphabetic (e.g., Chinese) scripts makes on reading and learning to read seem different. For example, Chinese writing differs from English alphabetic writing not only in the way graphic units are mapped to linguistic units (phoneme-level mapping in English and syllable-level mapping in Chinese), but also in its visual form (such as spatial configuration of stroke sequences in Chinese). Both, alphabetic and Chinese reading engage phonology as universal components but the procedures that lead to its pronunciation depend on the linguistic units inherent in the writing system (For a summary see Perfetti et al., 2013). While the retrieval of meaning from written units thus seems universal across writing systems, the retrieval processes may differ across writing systems. For example, in Chinese retrieving the meaning for a word may be triggered by a semantic radical that is part of the character or by the whole character.

Do the neural systems for reading reflect this duality, that is, universality on the one hand and writing system differences on the other? Contrasting English and Chinese reading has indicated that visual processing activates posterior (occipital and occipital-temporal) areas for both languages. However, while alphabetic writing shows strong left-lateralized effects in visual

Figure 4 The result of brain activations in response to reading comprehension tasks based on small stories for children aged 4–12 years (VWFA, visual word form area). Figure from Berl, M.M., et al., 2010. Functional anatomy of listening and reading comprehension during development. Brain and Language 114 (2), 115–125; Legend and labeling by Stemmer, B., based on Berl et al., 2010.

areas (including the VWFA), Chinese writing shows additional activation of visual areas in the right hemisphere (see Figure 5). The latter effect has been interpreted as reflecting the spatial configuration of Chinese character components. In addition, Chinese reading consistently shows greater activation in left frontal brain regions (including Broca's area) (Perfetti et al., 2013; Wu et al., 2012). This has been interpreted as reflecting higher demands of character composition or lexical selection through an orthographic memory in Chinese reading (Perfetti et al., 2013).

The Illiterate Brain

According to the United Nations Educational, Scientific and Cultural Organization's global monitoring report for 2013, 4774 million adults are still illiterate, two-thirds of which are women, with the highest numbers in India followed by China. Most Western-industrialized countries show a high literacy rate, although exact data are missing. According to the US Department of Education, in 2003 (the latest year data were available) 14% of US adults, that is about 32 million, lacked basic prose

Figure 5 Brain areas that support reading in English and Chinese. Activation for both systems is seen in left hemisphere posterior regions that support visual identification and left-hemisphere parietal region that may support graphic-to-linguistic mapping. Differences between the two systems include greater activation for Chinese of right-hemisphere posterior areas that support character identification and greater activation in frontal area that may support selection of character connections to meaning and pronunciation. Cross-hatches mark areas more involved in English than Chinese reading (IFG and STG). Areas with white backgrounds are involved in Chinese more than English. Areas with black backgrounds (IPL, FG) are involved in both Chinese and English for adults. Figure and legend taken from Charles Perfetti, et al., 2013. Specialization and universals in the development of reading skill: how chinese research informs a universal science of reading. Scientific Studies of Reading 17 (1), 5–21. doi: 10.1080/10888438.2012.689786.

literacy skills. A question, one may ask is whether the brain of those who have not learned to read at a young age and remained illiterate is organized differently compared to literate people. One of the few studies addressing this issue compared illiterate Brazilian and Portuguese adults who had never learned to read with ex-illiterates who had received adult alphabetization classes and achieved a modest level of literacy. Another comparison group was literate adults of the same socioeconomic background (Dehaene et al., 2010). It was observed that the VWFA was massively affected by literacy, to the extent that by simply measuring the brain activity, the researchers could predict a large proportion of the variance in the number of words the people could read per minute (see **Figure 6**) (Dehaene, 2013; Dehaene et al., 2010).

During the acquisition of literacy, activation in the planum temporale, the VWFA and the visual cortex increased. At the same time, activation also increased in occipital regions in response to all sorts of other nonreading-related visual stimuli. This was interpreted as indicating that other visual processes seem to profit from the acquisition of literacy and become more accurate and efficient. Another observation was that the network for spoken language also changed under the influence of reading in the sense that less activation was observed. This was interpreted as indicating that reading facilitates the comprehension of complex sentences and requires less effort in literate people. It was further suggested that a pathway (the arcuate fasciculus) connecting the posterior temporal regions of the brain (including the VWFA) with inferior parietal and frontal brain regions may link visual and phonological areas and play a role in grapheme-to-phoneme conversion (Dehaene, 2013). Studies like this are difficult to perform and it is thus not surprising that only a relatively small number of people were investigated. Replication of the study with a larger number of people is needed to strengthen the authors' arguments.

Reading in the Blind

In sighted people, reading relies on visually identifying letters. When blind people use Braille, visual letter identification is replaced by a tactile system (raised dots arranged in columns). Braille reading involves the control of finger movements, the

Figure 6 The figure shows the effects of literacy on the brain in response to written sentences. The horizontal and sagittal brain slices show the regions that were modulated by reading performance during the viewing of simple sentences. A large effect can be seen in the left occipital-temporal site (including the classical VWFA) and right occipital sites. Reading performance also modulated a vast left-hemisphere language network. The plots report activation to visual checkers, spoken and written language relative to rest in arbitrary units. Colored labels refer to participant groups and are ordered according to reading performance (LB1, LP, LB2 = literates; EXB, EXP = ex-illiterates; ILB = illiterates; VWFA = visual word form area). Figure taken from Dehaene, S., Pegado, F., Braga, L.W., Ventura, P., Filho, G.N., Jobert, A., et al., 2010. How learning to read changes the cortical networks for vision and language. Science 330 (6009), 1359–1364. Figure on p. 1360. Legend by Stemmer, B., based on Dehaene et al., 2010.

Figure 7 Panels (a) and (b) show the brain activation during normal reading of sighted individuals. Panels (b) and (c) show the brain activation when congenitally blind individuals were reading using soundscapes. Extensive bilateral activation of the ventral visual cortex including visual word form area (VWFA) can be seen when letter reading was compared to baseline (a and c), and left activation of the ventral visual cortex including VWFA when letter reading was compared to all other categories of visual stimuli (b and d). Figure taken from Striem-Amit, E., et al., 2012. Reading with sounds: sensory substitution selectively activates the visual word form area in the blind. Neuron 76 (3), 640–652. Legend by Stemmer, B., based on Striem-Amit et al., 2012.

perception of raised dots and the recognition of the pattern in which these dots are arranged. The tactile information must then be converted into meaningful patterns that have lexical and semantic properties (Sadato, 2005). Processing of tactile information usually recruits the somatosensory region of the frontal-parietal cortex while the processing of visual information (such as reading) involves the primary and secondary visual areas in the occipital cortex. When people who are blind from birth read Braille (that is use their fingers to touch the raised dots), the major activity detected by functional brain imaging is not, as one may expect, in the somatosensory area where touch is usually processed, but in the visual areas of the occipital lobe (for a summary, see Amedi et al., 2005). A similar observation was made for the auditory modality. Usually, sounds activate the auditory cortex in the temporal lobe. However, when congenitally blind individuals were 'reading' using the auditory modality via a system that converted the environment to auditory sounds, so-called soundscapes, regions in the ventral visual cortex, including the VWFA, were activated (Striem-Amit et al., 2012) (see **Figure 7(b) and 7(d)**). One explanation for these transfer phenomena is that the traditionally visual areas create new sensory associations and connectivity patterns and are thus recruited for some other function such as processing touch or auditory input. An alternative explanation is that the occipital lobe is inherently equipped for various functions but that these functions are normally inhibited in sighted people and are only revealed by visual loss (Amedi et al., 2005).

Abstract

Humans are social animals and the human brain is simultaneously adapted to facilitate social interaction and to be shaped by it. Many brain processes and regions contribute to social development. This article will discuss anatomical changes that occur during human development as well as functional roles of key brain regions.

Introduction: The Situated Brain

For the duration of our lives, our brains are influenced by the social world. Neonates begin learning about the world by watching their parents. These interactions help shape their brain formation. In fact, sociocultural influences play a large role in human brain development and processing across the life span. Under extreme circumstances, this influence can be deterministic and limiting. For example, infants kept in prolonged social isolation exhibit underdeveloped brain formation and fail to acquire basic motor skills or language (Rees, 2008; Watts-English et al., 2006; Lin et al., 2005; Hildyard and Wolfe, 2002; Perry, 2002; Perry and Pollard, 1997).

However, even under normal circumstances, the social environment influences epigenetic and endocrine processes (Curley et al., 2011; Champagne, 2010) and shapes neural pathways (Rule et al., 2013). Clarke and Chambers (1998) posit that the mind is 'extended,' meaning that it is embodied, enacted, situated, and distributed. The same can be said about the brain's relationships with the body and the world. Biological processes influence the brain's responses, potentials, and limitations, while social interactions and the greater environment provide stimuli for the brain to respond to. In each of these cases, a rich interplay between converging social and biological processes influences neural function and response.

The Culture-Brain-Behavior Interaction model (Crafa and Nagel) characterizes this interplay in terms of a feedback loop between social, neural, cognitive, and behavioral processes. When people encounter new social situations or information, learning occurs. This learning, however subtle, has the potential to alter, relax, or constrain psychological, neural, and biological processes. Likewise, these processes filter what is learned. This bidirectional interaction produces traces of culture in these processes but also accounts for individual variability.

This article will focus on two aspects of that feedback loop, specifically the relationship between human social development and the brain. When relevant, related biological processes will be discussed. Since other article in this encyclopedia address language development, this article will primarily discuss neural processes related to nonverbal social interactions and other fundamental features of human development that make social interaction possible, as well as some complex processes, such as those underlying empathy and identity. The relationship between neural processes and culture will also be discussed.

Structural Brain Development: Infancy through Early Adulthood

Human brain development begins during gestation, when the first neurons form and migrate toward different areas of the developing brain, and eventually differentiate and specialize in key neurophysiological processes (Perry, 2002; Rakic and Lombroso, 1998). At birth, neonates already have approximately 100 billion neurons, nearly the same as adults. However, the brain only weighs approximately 25% of what it will weigh in adulthood. During the first 3 years of life synapses, the connections between neural cells rapidly develop and the connectivity between neurons and brain regions exponentially increases. Myelination, the development of fatty tissue that insulates and lubricates neural processes, also begins. During the first decade of life, the human brain also undergoes substantial anatomical growth and changes in gray matter and white matter (Blakemore, 2008; Webb et al., 2001). Synaptic pruning occurs during childhood and adolescence, during which time nearly half of the synapses developed during early childhood are discarded while new synapses are formed. Myelination, on the other hand, continues to develop into adulthood. These changes produce reductions of gray matter and increases in white matter volume and integrity into adulthood, normally stabilizing around the mid-20s (Giorgio et al., 2010; Blakemore, 2008).

Social experiences play distinct roles in human brain development. Children who are raised in conditions of extreme neglect or isolation exhibit smaller brain volumes and fail to develop normal motor and social skills (Perry, 2002). Both synaptic and myelin development are affected by life experiences (Shonkoff and Phillips, 2000). Adequate nutrition and guardian attention are required for normal brain development. Some studies demonstrate that maternal touch during early infancy may improve cognitive processes and benefit brain development (Weiss et al., 2004). Other social interactions also help the child make necessary developmental progress, such as acquiring adaptive motor and language skills (Meltzoff, 2007). For example, the more a child is exposed to speech, the stronger these neural connections become; whereas, less exposure can cause these neural connections to diminish (Perry, 2006). Accordingly, acute isolation, emotional trauma, or stress can

play inverse roles in brain development, potentially inhibiting key processes (Shonkoff and Phillips, 2000).

The Social Brain: Functional Brain Processes

The 'social brain' commonly refers to brain regions that are involved in social cognition. Certain injuries can cause social impairment or disrupt normal social functioning, leading researchers to conclude that social cognition is unique from other types of neurocognitive processes (Grossmann and Johnson, 2007). Key areas of the social brain include the superior temporal sulcus (STS), anterior cingulate cortex (ACC), medial prefrontal cortex (mPFC), inferior frontal gyrus (IFG), as well as the anterior insula and the amygdala (Blakemore, 2008; Frith and Frith, 2007.).

These brain regions play functional roles in social cognition. Human infants are born ready to learn through social experiences with other humans (Csibra and Gergely, 2006). Neonates are born with multiple tendencies that facilitate social interaction, such as natural abilities for eye contact, face recognition, and emotional processing, as well as attentional preference for biological motion. Other social abilities, such as perception of others, joint attention, and prosociality, develop during infancy and early childhood. Adolescence is a time of rapid change in the social brain, affecting basic social abilities like facial recognition, self-awareness, and theory of mind. These abilities correspond with specific neural activity that appears to simultaneously facilitate and accommodate the social environment.

Recognition of Others: STS

Beginning at birth, human neonates demonstrate attentional preferences for human faces and eye contact (e.g., Farroni et al., 2005). This innate preference for the eyes and the face helps infants to bond with their parents to learn salient behaviors. Studies in adult humans have shown that the STS (**Figure 1**) is active when viewing faces (Blakemore, 2008). The STS has also been implicated in processing biological motion. Like eye and face gaze, having a preference for biological motion is advantageous to the infant for identifying important social and environmental information. Likewise, studies have demonstrated similar responsiveness of the STS when viewing biological motion (Blakemore, 2008; Saygin, 2007). Together, these studies point to an important role of the STS in processing these conspecifics, and in the recognition of other humans more generally. These processes are considered foundational for human social interaction, in part because they are innate abilities and in part because they act as building blocks for more complex social processes.

One of these processes is mentalizing, i.e., the ability to understand the internal states of others. Studies recording brain activity during mentalizing frequently report STS activity (Vander Wyk et al., 2009; Blakemore, 2008). Currently, there is some debate about how to precisely interpret this activity (Blakemore, 2008). On the one hand, given the role of the STS in processing conspecifics, it follows that it may play a similar role in mentalizing. Specifically, Saxe (2006) proposes that the STS may interpret the goals of others based on their body movements. Frith (2007), on the other hand, proposes that the role of the STS is limited to the anticipation of future movements of these conspecifics. While this predictive role facilitates mentalizing, it may not directly interpret the actions it is predicting. STS activity in mentalizing is stronger in U.S. children than Japanese children during word-based stimuli; whereas, Japanese children show higher STS during cartoon mentalizing tasks (Han and Northoff, 2008). Some researchers suggest that this could be due to the different role of disposition across cultures. While U.S. cultures tend to value disposition, environmental factors and social context appear to play larger interpretive roles in many East Asian cultures (Ames and Fiske, 2010).

Figure 1 The superior temporal sulcus (STS), indicated here in red, is the crevice on the surface of the temporal lobe that separates the temporal gyrus from the middle temporal gyrus. "Brain 01" (http://openclipart.org/detail/35791/brain-01-by-anonymous) by Anonymous is licensed under CC BY 2.0 and modified incompliance with this license agreement.

Emotion and Response Selectivity: ACC

The ACC (**Figure 2**) has also been implicated in understanding internal states of other, particularly in terms of emotion processing. Many studies of the ACC demonstrate that it is active when processing the emotions of other as well as when generating emotional responses. Early studies of the ACC suggest that it helps to determine the intensity of an emotional experience and ties it to emotional response regulation (Lane et al., 1998; Wilson and Chang, 1974). More recently, it has been associated with many high-level processes, including attention and behavioral response selection. Lane et al. (1998) propose that the ACC's role in emotion processing may be a by-product of these high-level processes. For example, the ACC appears to become more active when information is personally relevant and positively valenced (Moran et al., 2006). Findings such as these demonstrate that emotion processing is implicit to ACC activity, and the observed response selectivity implicates the

Figure 2 The anterior cingulate cortex (ACC), highlighted in red, occupies the frontal portion of the cingulate cortex. Figure 3 The medial prefrontal cortex (mPFC) in red sits adjacent to the anterior cingulate cortex (ACC) and occupies the highlighted portion of the prefrontal cortex, which makes up a majority of the frontal portion of the brain. "58294main_The.Brain.in.Space-page-157-brain" (http://openclipart.org/detail/38533/-by-rejon-38533) by rejon is licensed under CC BY 2.0 and modified incompliance with this license agreement.

ACC as a key player in social reward. Other studies demonstrate a bidirectional response to valence. For example, ACC activity in adults increases during social rejection and corresponds with the strength of reported pain the rejection has caused (Eisenberger et al., 2003, 2007). Such findings demonstrate that the ACC may selectively respond to any emotion that is personally relevant. Likewise, it selectively chooses how to respond. Given its selectivity, ACC activity appears contingent on the social norms and expectations of an individual. Considering that norms and expectations are often heavily influenced by social context and cultural background, ACC activity likely also varies partially as a function of culture, which may be an interesting topic for future research.

Knowledge of Self and Others: mPFC

Like the ACC, the mPFC (**Figure 3**) has also been implicated in emotion processing. The mPFC helps to determine the appropriateness of an emotion based on contextual cues, and control the degree and longevity of its expression (Etkin et al., 2011). However, the mPFC is best known for its role in 'self' processes more generally, such as self-control and self-identification. The mPFC has been shown to preferentially respond to personal preferences and values. For example, activity in the mPFC increases when identifying behaviors or values that describe oneself (Lombardo et al., 2010; Chiao et al., 2009). However, mPFC activity appears to be contingent on personal values. Studies comparing people who value individualism with those who value collectivism demonstrate that, when someone values collectivism, the mPFC responds to questions pertaining to both self and a close other (e.g., one's mother) with similar activity increases. In contrast, the mPFC preferentially processes only self-information when a person values individualism. During adolescence, a critical time for the development of personal identity, mPFC activity is often linked with decisions whether or not to engage in risky behavior. Several studies report that teens who take more risks have heightened mPFC activity during risk-taking experiments. Other studies show that teens who refuse to take risks show greater mPFC activity. This apparent contradiction potentially suggests that the decision to take risks may relate to personal identity.

Activity in the mPFC is theorized to facilitate interpretation of others by using oneself as a reference. One study, for example, showed that seeing oneself performing an action facilitates interpretation of the emotions of others (Li and Tottenham, 2011). In this study, participants who viewed their own faces before viewing the faces of others showed increased emotion recognition. These findings support the idea that self-information facilitates mentalizing about others. Additionally, these findings show that embodied self-representations facilitate other-mentalizing, which suggests that some high-level areas may be employed when viewing embodied information. In order to better understand the role of self-information in learning and mentalizing, the underlying processes must be further explored.

Self–Other Mapping: IFG

The IFG (**Figure 4**) is part of the mirror neuron system, a network of brain areas that are hypothesized to facilitate social cognition and action imitation. Like the ACC and mPFC, the IFG appears to play a role in interpreting others. In contrast with these two other brain regions, the IFG appears to specialize in social perception pertaining to movement and action imitation. Disruption of IFG activity makes imitation more difficult, and also reduces accuracy when interpreting the actions of others (Keuken et al., 2011). The IFG is also selectively active in response to facial emotional cues, and

Figure 4 The inferior frontal gyrus (IFG), shown here in red, is a cleft in the prefrontal cortex, which is bordered by the inferior frontal sulcus, the lateral fissure, and the inferior precentral sulcus. "Brain 01" (http://openclipart.org/detail/35791/brain-01-by-anonymous) by Anonymous is licensed under CC BY 2.0 and modified incompliance with this license agreement.

appears to be essential for processing motion-based social information (Dapretto et al., 2006).

Specialized Emotion Areas: Anterior Insula and Amygdala

Both the anterior insula and the amygdala (**Figure 5**) are involved in emotion processing and are usually active when interpreting any emotional cue (Lamm and Singer, 2010). However, these regions are perhaps best known for being particularly sensitive to certain emotions. Multiple studies link anterior insula activity with expressions of disgust, and one study even showed that the amplitude of its activity corresponds with the expressed magnitude of disgust (Phillips et al., 1997). The amygdala, on the other hand, specializes in fear and aggression, and hyperactivity of the amygdala can cause difficulty in interpreting emotional faces (Schultz, 2005). Disgust and threat are both fundamental emotions that help to extend longevity, by influencing what we avoid eating and when we protect ourselves. Although these basic emotions can be found in every culture, the defining features of gross and threatening things vary widely. For example, eating the eyes or brains of an animal is widely accepted in some parts of the world and considered disgusting in others. Similarly, hitchhiking is considered safe in some countries but can be very dangerous in others. Such cultural variability suggests that anterior insula and the amygdala activity likely vary according to a person's social context and cultural background.

Neural Plasticity and Sociocultural Learning

Neural plasticity is a key component of human brain development, and necessary for social learning. Neural plasticity refers to the brain's innate ability to form new synaptic connections as well as to alter or eliminate existing ones. Learning that occurs from new social experiences leads to these synaptic changes (Black, 1998). This ability is so dynamic that the brain is sometimes able to compensate for severe damage, such as traumatic injury or stroke, by recruiting other brain areas to perform the functions the damaged areas are normally responsible for. This flexibility is ubiquitous in the brain; although, it is less often observed in areas that control basic functions such as heart rate. Neural plasticity theoretically makes it possible for people to learn appropriate sociocultural behaviors during childhood as well

Figure 5 The anterior insula (left) cannot be easily seen via diagrams of the brain because it is positioned under the surface layer of the cerebral cortex, in approximately the highlight location. The amygdala (right) is located in the temporal lobe. "Brain 01" (http://openclipart.org/detail/35791/brain-01-by-anonymous) by Anonymous is licensed under CC BY 2.0 and modified incompliance with this license agreement; and "58294main_The.Brain.in.Space-page-157-brain" (http://openclipart.org/detail/38533/-by-rejon-38533) by rejon is licensed under CC BY 2.0 and modified incompliance with this license agreement.

as to adapt to new customs and changing social environments as an adult. Reduced plasticity has been observed in people with social and mental impairments, suggesting that plasticity's role is fundamental for normal human social development (for review, see Zatorre et al., 2012).

Challenges and Opportunities for Developmental Social Neuroscience

Social neuroscience is a prominent and expanding field, within which developmental research is a crucial subset. Despite the vast body of literature that has accumulated since the field's inception, a majority of this research comes from North America and Western Europe. Considering that social cognition and related brain activity are largely contingent on immediate social context as well as individual cultural background, social neuroscience research is potentially very specific to the population being studied. The underrepresentation of many global populations in research studies may limit the generalizability of certain findings. Known cases of this have been discussed throughout this article; however, cultural variations in neural processes are only beginning to be studied. This may be, in part, for practical reasons. Until recently, conducting cross-cultural research posed many logistical challenges, including inadequate resources as well as communication barriers, and often required expensive travel. However, international collaborations are occurring with increasing frequency, and communications tools such as Skype help close the distance. Future research should focus on representing populations outside North America and Western Europe, with an eye toward understanding human diversity in the social brain.

Closing Remarks

Despite the challenges it may face, developmental social neuroscience provides numerous insights into the neurobiological processes that facilitate social interaction. These processes are fundamental for interpreting the actions, intentions, and emotions of other people. They situate our brain within the social world, allowing us to learn from others and others to learn from us. These are fundamental mechanisms underlying some of the most precious moments in life. Through understanding them, we come closer to understanding ourselves and our species.

Abstract

Moral behavior is one of the most sophisticated human abilities. Many social species behave altruistically toward their kin, but humans are unique in their ability to serve complex and changing societal needs. Cognitive neuroscience has started to elucidate specific brain mechanisms underpinning moral behavior, emotion, and motivation, emphasizing that these ingredients are also germane to human biology, rather than pure societal artifacts. The brain is where psychosocial learning and biology meet to produce the rich individual variability in moral behavior. This article discusses how cognitive neuroscience improves the understanding of this variability and associated suffering in neuropsychiatric conditions.

Introduction

The terms moral and ethical derive from their respective Latin and Greek roots (*moralis* and *ethikos*). Literally, they would probably be best translated as in accordance with societal customs. Based on this, the authors have suggested an operational definition of moral behavior as behavior that is in accordance with other people's needs or sociocultural norms (Zahn et al., 2011). Moral behavior requires at least two components: (1) knowing about sociocultural norms and the needs of others and (2) being motivated to act on this knowledge (Zahn et al., 2011). Distinguishing moral from selfish motivations in real life is often difficult, and cooperation in societies is usually not sustained on the basis of moral motivations alone. Instead, such morally motivated behaviors intermingle with self-serving ones that sustain individual survival in a complex interplay that often helps stabilize productive relations in social groups. Such behaviors essentially include codes of reciprocity (described in the economic and evolutionary literature, as a direct or indirect gain for somebody for cooperating in a society (Nowak and Sigmund, 2005)). Societies have therefore developed external reward and punishment systems, nowadays enshrined in law, work ethics, and other organizational regulations, to enforce behavior in accordance with communal welfare.

Computational models have shown that individual variability in moral behavior may have sustained cooperation in small social groups that preceded our modern societies (Boyd et al., 2003; Boyd and Richerson, 2009). These studies suggest that in the absence of law enforcement systems, cooperation can only be sustained if at least a fraction of individuals are motivated to risk substantial resources in order to punish other individuals who behave immorally. Were these individuals perfectly economically 'rational' and purely selfishly motivated, there would be no incentive to do so in that they would usually lose more than they would win. Such costly behaviors have been referred to as 'altruistic punishment.' In these models, selfishly motivated individuals, known as 'defectors,' are kept in check by the 'altruistic punishers.' A third type of agents will contribute own resources to the community ('contributors'). The debate in evolutionary sciences is how the genes of people who sacrifice their own resources could have survived evolutionary pressures. This is easy to explain in the small groups from which we are thought to originate, based on kinship-based genetic relatedness mechanisms. Thus, everything that was beneficial to the survival of the group would benefit the duplication of the gene pool, relative to individuals belonging to other small-scale societies. However, many evolutionary theorists need to explain sacrifices of one's own resources in large-scale modern societies by nonmoral motivations, reverting to at least indirect benefits of cooperation for oneself or one's family (West et al., 2007). This is because they disagree with the argument of group selection benefits, which is supported by Boyd et al., whose model proposes that cooperative societies enhance the survival chances of their genes in competition with noncooperative ones even in the absence of intragroup genetic relatedness. This view is also adopted by researchers performing neuroeconomic experiments to demonstrate altruistic behavior among strangers in the absence of direct or indirect benefits (Gintis et al., 2008).

While it is beyond the scope of this chapter to delve into this fascinating debate further, important implications for the neuroscience of morality can be derived:

1. If gene selection has promoted moral motivations within societies, then these genes must have influenced brain mechanisms that support moral behaviors, because biological influences on human behavior are mediated by the brain.
2. If this was indeed the case, then those brain mechanisms must have also allowed for adaptation through cultural learning that allowed individuals to adapt to changing sociocultural environments, because the same behavior can be adaptive and maladaptive depending on cultural and situational contexts (e.g., 'killing in war' and 'killing in peacetime').
3. If individual variability in moral motivations was necessary to provide group survival advantages, then one should be able to identify different types of brains supporting different inclinations toward different balances of moral and selfish

motivations that are further shaped by cultural learning. This would then allow for individuals ranging in their motivational inclinations from selfish to different degrees of preparedness to moral punishment or cooperation.

This article will provide an overview of the human brain mechanisms that appear to be selective for moral as compared with selfish motivations (Section Cognitive-Anatomical Basis of Moral Motivation) thereby addressing the first question. The authors further devote a section to brain mechanisms underpinning social knowledge to address the second question (Section Cognitive-Anatomical Basis of Social Knowledge). They take the perspective here, that social knowledge can be used for moral as well as selfish purposes (e.g., manipulation and reputation gain) and is therefore not selective for the moral domain. To address the third question, the authors discuss evidence supporting individual differences in the neuroanatomy of moral motivations and relate this to the question of how these may contribute to mental health and suffering (Section Implications for Differential Vulnerability in Psychiatry). A large proportion of us suffer from psychiatric disorders at least once during our lifetime, for example, depression is estimated to affect 151 million people around the world (Funk, 2010). Our risk is significantly influenced by genetic factors as shown by studies comparing mono- and dizygotic twins (Kendler, 2006). Given the large number of affected people, it is tempting to speculate whether some psychiatric risk genes have carried advantages for psychosocial functioning and survival in order to be selected for by evolutionary pressures. If it is the variability between individuals within societies that makes these function most adaptively, this could explain the variability in how people navigate in the social world. This variability could then explain vulnerability to different types of mental health problems depending on the demands of one's social environment. Some evolutionary thinkers support the idea that risk genes for psychiatric disorders could have adaptive functions through group selection (Wilson and Wilson, 2007). Others, in contrast, have argued that the polygenetic nature of these risk genes and their complex interactions with environmental factors can explain the high frequency of psychiatric disorders, despite their proposed evolutionary maladaptiveness (Keller and Miller, 2006).

Brain mechanisms that influence social cognition and behavior are based on macroanatomical, microstructural, and neurochemical components that are employed to learn and adapt to complex information in our psychosocial environment. The advent of moral neuroscience was the discovery that disruptions of the macroanatomical structure of brains could lead to marked changes in moral behavior (Section Moral Behavior in Patients with Macroanatomical Brain Lesions). Microstructural changes were documented in postmortem studies of conditions such as autism (Casanova et al., 2002), a disorder of social cognition in general rather than moral cognition more specifically. Due to the difficulty in obtaining such data, however, there is not enough evidence on microstructural changes tied to moral behavior to be included here. Functional magnetic resonance imaging (fMRI) has been employed since the 2000s to study moral cognition and emotion. While this has provided us with a rich set of data, its interpretation needs cautious validation from lesion studies. This is because the results of functional activation-based neuroimaging depend as much on the psychological task conditions as they do on brain structure and function. fMRI, however, provides a unique opportunity to measure psychobiological interaction thereby capturing the results of brain adaptations to psychosocial learning (Section Functional Neuroimaging of Moral Cognition and Emotion). Electrophysiological properties of the brain are probably closest to human experience and novel techniques of analyzing electroencephalography and magnetic encephalography have opened up great possibilities. The evidence base using these techniques in moral cognition is still quite narrow and will therefore not be reviewed here. Transcranial magnetic stimulation is a way to simulate brain lesions and has been employed in moral neuroscience, but its use is restricted to areas near the skull surface and thereby does not allow for a systematic study of several of the brain regions known to be relevant from patient lesion studies. Neurochemical influences on moral cognition and emotion have been reviewed elsewhere and are beyond the scope of this article (Moll and Schulkin, 2009). Finally, the authors will not review correlations between gene polymorphisms with neuroimaging data. This is because the focus of this article is on understanding the neural rather than the genetic prerequisites of moral behavior. Section Cognitive-Anatomical Models of Moral Cognition and Emotion briefly summarizes the conflicting neurocognitive models of moral cognition and emotion and lays the ground for future directions for research.

Moral Behavior in Patients with Macroanatomical Brain Lesions

In 1888, Leonore Welt, a Swiss physician, reviewed a series of patients with damage to the frontal cortex, who showed marked changes in moral character as judged by their jocular childish or aggressive behavior (Welt, 1888). Interestingly, their general intelligence was preserved. Phineas Gage, the now famous US American patient (Damasio et al., 1994), with an iron-bar injury to his medial frontal lobes was one of the cases reviewed by Dr Welt. Based on postmortem neuropathology and injury pattern, she concluded that the most consistent structure damaged in all cases was the right medial orbitofrontal cortex. While this was probably the first systematic evidence for a causal role of specific brain structures for enabling moral behavior, it also marked the beginning of a controversy about the function of the frontal lobes. This is because systematic studies of patients with head injuries during the First World War confirmed earlier case reports of some patients with frontal lesions and no behavioral change (Teuber, 2009). This lack of impairment in some patients could of course be explained by insufficient characterization of the lesion or lack of sensitivity of clinical observation. However, it could also point to individual variability in cognitive-anatomical architecture leading some patients to be more sensitive than others to frontal brain lesions.

In the 1980s, brain computed tomography became available in clinical settings and led to a renaissance of neuropsychological case studies. Eslinger & Damasio sparked new

interest in the neural basis of behavior counter to moral rules by describing EVR, a patient with ventral frontal lobe damage due to tumor resection (Eslinger and Damasio, 1985). He exhibited difficulty in making daily life decisions and made choices that led to a ruin of his financial fortunes as well as his marriage. At the same time, he showed normal functioning on classical tests of executive functioning such as the Wisconsin Card Sorting test, which is usually impaired in patients with left dorsolateral frontal lesions, which was not damaged in EVR.

In the same decade, a neurodegenerative disease, originally described by Arnold Pick in the late nineteenth century, became recognized as a relatively common form of early-onset dementia that could be reliably diagnosed before death (Snowden et al., 2001). These patients exhibited varying degrees of frontal and anterior temporal atrophy captured in the term 'frontotemporal lobar degeneration.' This led to cumulating evidence on inappropriate social behavior in these patients (Bozeat et al., 2000) that was independently associated with right anterior temporal and ventromedial frontal atrophy (Liu et al., 2004). Patients with right anterior temporal lesions behave as inappropriately as patients with ventral frontal atrophy. For example, in their clinic, the authors saw a patient (further referred to as 'the singing lady') with isolated right anterior temporal lobe atrophy, who lost her job, because of kissing and singing to customers at work, who also sang happy birthday to her parents on the cemetery.

Studies in patients with brain lesions were often hampered by the lack of neuropsychological tasks that could probe cognitive functions relevant to the observed behavioral changes and largely relied on carer reports. Loss of guilt was reported by carers of patients with ventromedial (prefrontal cortex) lesions (Koenigs et al., 2007) and neurodegeneration in this area, which included the subgenual cingulate cortex, was associated with loss of interpersonal warmth as judged by carers (Sollberger et al., 2009). Inappropriate behavior in these patients often goes against societal needs or needs of others and therefore clearly has moral implications. However, the disruption of which cognitive and emotional components leads to this behavioral change is disputable. Patients with ventral frontal lesions were found to show intact social knowledge when asked about their behavior (Saver and Damasio, 1991; Eslinger and Damasio, 1985). Similarly, Mendez et al. found in their patients with frontotemporal lobar degeneration that knowledge of moral rules was intact when assessed on a questionnaire, but nevertheless patients failed to act on these rules (Mendez et al., 2000). This may lead to the hypothesis that moral motivation and knowledge may be at least partly dissociable. The hypothetical causes of socially inappropriate behavior are

1. Loss of (access to) knowledge of appropriate social behavior (Zahn et al., 2009b).
2. Loss of the moral motivation to act upon intact social knowledge (Moll et al., 2005b).
3. Loss of the ability to suppress urges/drives (Brutkowski, 1965) with intact social knowledge of their inappropriateness and intact moral motivation to act upon this knowledge.

In order to test these different possibilities, one needs to probe moral motivations experimentally while controlling for social knowledge and vice versa. Two studies in patients with frontotemporal lobar degeneration have used this approach. One study showed that patients with damage of the right anterior temporal lobe displayed selective deficits on abstract knowledge of social behavior (i.e., social conceptual knowledge, e.g., what it means to act 'tactfully') relative to nonsocial conceptual knowledge (e.g., what it means to be 'nutritious,' Zahn et al., 2009b). Furthermore, selective deficits on social concepts were associated with inappropriate social behavior. The social concept discrimination task used to probe this particular type of social knowledge did not require moral motivations and controlled for the effects of positive or negative emotional valence. Interestingly, the right anterior temporal lobe atrophy patient, 'the singing lady,' exhibited a selective impairment on social concepts with relatively intact nonsocial concepts when using this test (Zahn et al., 2012).

Another study showed that patients with frontotemporal lobar degeneration and relatively stronger involvement of the septal area were selectively impaired on a task probing guilt and pity, relative to other negative emotions such as embarrassment, disgust, and anger (Moll et al., 2011). The task controlled for the degree of social knowledge required by using similar statements to describe social situations in which one usually feels a particular moral feeling (e.g., "Your mother calls you one night, telling you she was not feeling well. You did not take her seriously and the next day she died" associated with guilt in 80% of a normative sample). Neurodegeneration of the frontopolar cortex was associated with selective loss of guilt, pity, and embarrassment compared with disgust and anger.

These studies, together with evidence from fMRI reviewed below, indicate that moral motivations and social conceptual knowledge are associated with dissociable brain regions and can thus independently contribute to inappropriate social behavior. The third and most popular explanation for such behavior, however, is that these patients know about other people's needs and are motivated to act on them, but that they have lost the ability to suppress selfish urges in subcortical regions that counteract their ability to act morally.

This frontal-subcortical suppression view probably became influential because of the way conditioning experiments in nonhuman animals were interpreted (Brutkowski, 1965). To the authors' knowledge, there is, however, no anatomical evidence supporting strictly unidirectional, inhibitory connections from frontal cortical to subcortical areas, which would support such a suppression mechanism. Furthermore, there is no evidence that selfish motivations are more dependent on subcortical than cortical mechanisms. On the contrary, there is evidence from case reports in patients with subcortical lesions that these may be associated with severe antisocial behavior. Subcortical lesion cases included hypothalamus, septal area, amygdala, and basal ganglia (Moll et al., 2003), but it is unclear how regularly these associations can be found. A more plausible version of the frontal-subcortical suppression model is mentioned below in which the frontal cortex is thought to control (Miller and Cohen, 2001) rather than suppress other areas of the brain.

In principle, one must consider another explanation for 'immoral' behavior after ventral frontal lesions, namely, that moral behavior requires more complex cognition and will thereby be nonspecifically impaired in large brain lesions. If this was the case, patients with similar degrees of brain damage and impairment should also show similar degrees of deviations from moral behavior. Interestingly, this is clearly not the case in that patients with Alzheimer's dementia in similar mild to moderate stages of the disease do show intact interpersonal behavior in the overwhelming majority of cases (Bozeat et al., 2000). Alzheimer's dementia typically leads to neurodegeneration of medial temporal, as well as medial and lateral parietal brain regions in these stages (Herholz, 2003). This means that moral behavior in a daily life context appears to be independent of these brain regions.

Functional Neuroimaging of Moral Cognition and Emotion

Introduction

When describing the function of a brain area, one can either describe (1) which type of task it is involved in carrying out (i.e., process-dependent description), (2) which information content it stores (i.e., content-dependent description), or (3) in which format it stores information (i.e., format-dependent description). The brain regions considered to be important for moral cognition and emotion were found to be involved in tasks and contents of different formats (e.g., visually presented pictures and written statements, reviewed in Moll et al., 2005b). However, because most people assume format independence of moral cognition and emotion, this was not rigorously investigated for most brain regions. Most fMRI studies of moral cognition and emotion have either taken a process- or a content-based approach to the design of their experiments. Describing a brain area as involved in a certain process or representation of a certain content is not very helpful in itself, unless one can make the case that there is some degree of selectivity of its involvement in that particular process or content compared with other processes or contents and other brain areas. This is because the less specifically a process or content is defined and tested, the more brain areas and cognitive components will be involved in it. So one could design experiments testing very broad functions, which will then involve a large set of brain areas, but this will not be very informative (i.e., add new information to what was known before). The authors have therefore focused on reviewing studies that chose experimental and control conditions in such a way that a high degree of selectivity of a given brain region for the function of interest could be derived. Claims of process selectivity are often not supported by generalizing across different types of contents and likewise content selectivity is often not supported by being tested across different tasks (processes). Future studies are needed to fill this gap. The broader involvement of a network of frontal, subcortical, and anterior temporal regions in moral cognition and emotion tasks, however, is generally agreed upon when considering the lesion and functional imaging literature (Moll et al., 2005b, 2008). In fMRI studies, posterior superior temporal, temporoparietal junction, and precuneus are also regularly activated in moral cognition and emotion tasks. The fact that patients with posterior cortical atrophy and Alzheimer's disease do not usually show grossly abnormal social behavior (see above) implies that the involvement of these regions must be more subtle and it is unlikely that they will show the same degree of selectivity for moral cognition and emotion.

Fronto-temporo-subcortical networks activated in response to morally relevant stimuli are highly overlapping with brain responses to other social cognition tasks (e.g., when having to think about mental states compared with physical inferences ('theory of mind') (Frith, 2007)). It is therefore important to define what distinguishes moral from social contents or processes. The authors define in this article social behavior as any type of behavior that has potential consequences for others. Thereby, any type of social behavior will have moral implications, subtle as they might be, in that it affects other individuals or society in general. Lonesome behaviors such as paper recycling at midnight when nobody watches are very good examples of social behaviors with moral implications in that the action of recycling motivating the action is driven by societal needs. When observing social behavior from the outside, there is therefore no way of distinguishing social from moral behavior. Only when hypothesizing about the different motivations driving these behaviors, it is that we are able to distinguish moral from selfish social behaviors. For example, unobserved behavior that supports societal needs such as a man recycling paper at night is more likely to be morally motivated than the same behavior with relevant others watching. For example, the recycling man could be motivated by trying to charm an ecologically conscious women observer whom he is sexually interested in. Thus, according to our definition here, what is special about moral relative to social contents and processes is their specificity for morally relative to selfishly motivated behavior. Selfish social behaviors require the same amount of mental state inferences as morally motivated social behaviors if they require manipulating other people. For both cases of morally or selfishly motivated behaviors, however, the level of engagement of social cognition mechanisms will depend on the level of the complexity of predictions about the effects of one's behavior on others and associated social interactions. Nevertheless, there is quite a large repertoire of selfish behaviors that are nonsocial and thus require much less complex cognition, because social interaction is generally more complex and contextualized. This may explain why impairments of general social cognition appear to impair moral behavior more than selfish behavior in general. One example is the right anterior temporal lobe atrophy patient, 'the singing lady,' mentioned before, who showed a selective impairment on social conceptual knowledge, which impaired her understanding of social situations and thereby led her to violate social rules with a relatively intact ability to help herself to food, play Sudoku puzzles, and appear quite happy in her mood. When reviewing the functional imaging literature, the authors will therefore include brain regions that show some selectivity for social compared with nonsocial cognition even if they are most probably not special for moral functions proper. The authors will not, however, focus on brain regions such as the left lateral parietal and left dorsolateral prefrontal cortices whose

specialization for social cognition is unlikely given the intact clinical appearance of social behavior in patients with focal lesions to these areas, such as aphasic stroke patients (Zahn et al., 2004).

Content-Based Subdivisions

At the broadest level, morally relevant contents were compared with nonmorally relevant contents. This included verbal statements or pictures rated by participants according to their moral relevance before the fMRI experiment. Obviously, it is important to control for the emotional relevance in those experiments, which was done in at least some of the studies. Taken together, frontopolar, ventral frontal, subcortical, and anterior and posterior temporal sulcus were most consistently activated when comparing morally relevant with morally irrelevant materials (reviewed in Moll et al., 2005b). The difficulty lies in identifying the functional contribution of each of these areas in that one could argue that socially relevant materials have been found to engage similar brain areas and it is unclear to what extent any of these areas is selective for moral cognition and emotion. Should they be involved in more general social functions, it is also unclear which exact contribution they are making to moral cognition and emotion. It is a matter of debate, how to best subdivide different categories of morally relevant contents. One approach is to distinguish between harm-, disgust-, and dishonesty-related (Parkinson et al., 2011) or justice- and care-related (Ochsner et al., 2004) moral contents and these were shown to be associated with differential brain activation patterns. The difficulty, however, is to demonstrate that complex moral scenarios used in these studies differed mainly with regard to these categorical distinctions, or whether there were associated differences in other nonmeasured variables.

The eighteenth century German philosopher Immanuel Kant distinguished the ability to judge what is morally right and wrong ("*principium diiudicationis*") from the motivation ("*principium motivationis*") to act morally (Kant, 1786/1903). He thereby anticipated a dissociation later found in some patients with ventral frontal brain lesions whose knowledge of how they should behave seems to be better preserved than their motivation to act accordingly (Eslinger and Damasio, 1985). The reverse dissociation can be observed as well. For example, the patient with a focal right anterior temporal lobe atrophy ('the singing lady') was selectively impaired on conceptual knowledge of social behavior as described before. Interestingly, she was among a minority of patients with frontotemporal lobar degeneration in which carers agreed that she appeared able to feel guilty. The authors probed this experimentally by giving her 22 sentences where she was described acting badly toward her best friend (negative self-agency condition: e.g., 'You act in a stingy way toward Jane'), in the negative other-agency condition, the authors just reversed the agents and recipients thereby keeping the social knowledge required to understand the sentences equal (e.g., 'Jane acts in a stingy way toward you'). Often, the patient did not understand what the concept (e.g., 'stingy') meant, but she was generally able to say whether it was a good or a bad thing to do (the most general form of social knowledge). After each sentence she was asked to say out aloud the feeling she would feel in this situation and was given a selection from guilt, anger, pride, gratitude, and none/other. This allowed her to respond with guilt in 73% of the negative self-agency trials, rarely responding with anger (5%) in this condition. In the negative other-agency condition, however, she showed the reverse pattern (68% of anger and 5% of guilt). It thus appears that if she was given the right cues, she was able to experience guilt, but because of her impaired social conceptual understanding, she would often miss the cues of the situation in real life. The sections below review fMRI studies that have contributed to a better understanding of the interlocking but partly independent neural systems underpinning social knowledge and moral motivation.

Cognitive-Anatomical Basis of Social Knowledge

Social knowledge has been defined as knowledge of one's own and other people's minds (Adolphs, 2009). Because 'mind' or 'mental states' are hard to break down neuropsychologically, the authors prefer defining social knowledge as denoting nonepisodic (i.e., semantic) knowledge of social sensory properties and social behavior (i.e., functions, see **Figure 1**).

There is growing consensus among neuroscientists investigating semantic knowledge of objects, that this requires not only the representation of modality-specific sensory and motor features of objects (e.g., 'the color of a robin,' 'the feel of its feathers'), but also a more abstract representation of the core aspects of what one means by, e.g., 'robin.' These core aspects are particularly important for understanding the behavior or functions of the things surrounding us. Based on evidence

Figure 1 The hypothesized neurocognitive components of social and moral knowledge are illustrated (modified from Zahn, R., Oliveira-Souza, R., Moll, J., 2011. The neuroscience of moral cognition and emotion. In: Decety, J., Cacioppo, J. (Eds.), The Handbook of Social Neuroscience. Oxford University Press). The authors refer to non-episodic long-term memory here and distinguish between sensory social knowledge presumably represented in the posterior superior temporal cortex and knowledge of social behaviors (i.e., functions). The latter is subdivided into two anatomically separable systems: (1) abstract conceptual (i.e., context-independent) knowledge of social behavior represented in the anterior temporal lobes (aTL) and (2) associative (i.e., context-dependent) knowledge of social behavior represented in frontosubcortical networks. Associative knowledge of social behavior is subdivided into a component representing knowledge of sequences of social actions (events) within frontopolar cortex (FPC) and ventral prefrontal cortex (PFC) (representing associations of action/event sequences with motivational/emotional states) and a subcortical mesolimbic component representing 'free-floating' motivational/emotional states (see also **Figure 4**).

from fMRI, repetitive transcranial magnetic stimulation, and a neurodegenerative disease of the anterior temporal lobes called semantic dementia (a subtype of frontotemporal lobar degeneration), the anterior temporal lobe has been identified as hosting this core representation of concepts that is independent of the context of the type of task, modality, or arbitrary associations (Ralph and Patterson, 2008). For example, 'greeting colleagues' is associated with 'cheek kissing' in Brazil, but people in Britain would not strongly associate the two at least in the context of British work life. Such context-dependent associations are important for context-appropriate social behavior.

Wood and Grafman provide an overview on evidence linking the frontal cortex with one particular type of associative context-dependent knowledge, namely, the knowledge of sequences of events and actions (Wood and Grafman, 2003). More specifically, they hypothesized that the ventral frontal cortex represents socially relevant knowledge of sequences of events and actions. This knowledge about the context of sequences of actions enables us to appropriately choose an action in one sequential context (e.g., 'cheek kissing of colleagues in Brazil'), but refrain from it in another (e.g., 'Britain'). This context-dependent appropriateness of many of our actions could explain why patients with ventral frontal lesions, one of the earliest and most consistently affected areas in frontotemporal lobar degeneration, do something that is inappropriate in a particular context, but not necessarily totally out of character. For example, the authors saw an 80-year-old lady with frontotemporal lobar degeneration from Manchester, who patted bottoms of men as soon as they bent down. This was despite not feeling any sexual desire. When the men turned around, she said: "Oh, I am sorry, I was just checking where your wallet was." Interestingly, her husband told us that she was patting other men's bottoms at parties when younger, but now this behavior had generalized to nonparty contexts.

fMRI studies have confirmed the hypothesis that regions within the anterior temporal lobes are selective for social versus nonsocial concepts and that this area stores these concepts in a context-independent way. Right superior anterior temporal activations were found irrespective of the context of emotional valence (negative, positive (Zahn et al., 2007, Zahn et al., 2009c)), agency (self or other (Zahn et al., 2009c)), and task (semantic (Zahn et al., 2007) or emotional judgment (Zahn et al., 2009c)). The localization of activations concurred with the lesion evidence reported above. Another study found a more middle anterior temporal area on the left side, which was shown to be more active for social concepts relative to nonsocial concepts as well as overlapping with a mentalizing task (Ross and Olson, 2010). Thus, anterior temporal lobe activations during mentalizing tasks (Frith, 2007) could be explained by accessing social conceptual knowledge to interpret the intentions of other people. Subsequently, the right superior anterior temporal lobe localization for social compared with nonsocial concepts has been independently confirmed (Skipper et al., 2011).

Direct evidence regarding knowledge of sequences of events and actions within the ventral frontal lobes from functional neuroimaging is still emerging. The medial frontopolar cortex (BA10), however, was activated when participants had to decide whether actions/events (e.g., 'order the food,' 'ask for the menu') were in the right or wrong sequential order. This activation was relative to a control condition of deciding whether the events were printed in the same or different font (Krueger et al., 2007). This task-dependent activation does not prove the existence of sequence-specific contents in this area, but an additional analysis in which the frequency with which events/actions occurred revealed that different subsectors of the medial frontopolar cortex were activated more strongly depending on frequency of occurrence in daily life. This is better explained by content-, rather than process-specific models, because response time did not explain these differences. Another study confirmed these results by showing that the medial frontopolar area was the only brain region to linearly increase activation with increasing complexity of event sequences (Krueger et al., 2009). One conundrum is how to explain relatively intact social knowledge in patients with ventral frontal lesions that often encompass the frontopolar cortex. A possible explanation is that the intact anterior temporal lobe representation of context-independent social knowledge may help these patients answer theoretical questions about appropriate behavior, but that in order to probe this knowledge of complex consequences of behavior as required for the execution of real actions, one will need to develop more refined ways of experimental testing.

Cognitive-Anatomical Basis of Moral Motivation

The term moral motivation was used by the eminent moral philosopher Francis Hutcheson (Bishop, 1996), who played an important role in highlighting the importance of what were later called 'moral sentiments' by Adam Smith (Smith, 1759/1966) – now mostly referred to as 'moral emotions.' Morally relevant materials will always be emotionally relevant (Haidt, 2001) unless one tries to take the perspective of an impartial spectator (Smith, 1759/1966). The same network of brain regions mentioned before to be selective for morally relevant compared with morally less relevant materials is therefore the starting point for the search of neural correlates of moral sentiments. Here, the authors summarize the evidence on those moral sentiments that were studied in more than two fMRI studies.

Guilt

The anticipation of guilt is thought to play an important role in preventing us from acting immorally and to motivate reparative action (Tangney et al., 2007; Eisenberg, 2000). The experience of guilt has been associated with activations of the dorsal cingulate in an early study (Shin et al., 2000), but this did not use an emotional control condition and does therefore not allow conclusions about guilt selectivity. Frontopolar activations were found most reproducibly for guilt while using different control conditions (other-critical feelings such as indignation (Moll et al., 2007; Zahn et al., 2009c); anger toward self (Kedia et al., 2008); embarrassment (Takahashi et al., 2004); regret with no consequences for others (Morey et al., 2012); and sadness (Basile et al., 2011)). The subgenual cingulate cortex (including the posteriorly adjacent septal area in some studies) was found to be selectively activated for guilt compared with indignation

toward others, but only when modeling individual variability in empathic concern (Zahn et al., 2009a), or guilt-proneness (Zahn et al., 2009c; Green et al., 2012). Interestingly, subgenual cingulate activations for guilt were independently reproduced (Morey et al., 2012; Basile et al., 2011). In contrast, another fMRI study found right lateral orbitofrontal and posterior dorsomedial prefrontal activations to be selective for guilt compared with shame and sadness (Wagner et al., 2011).

Pity (Compassion, Sympathy)

Emotional empathy and pity are very closely related and empathy has been extensively studied using neuroscience methods (Decety and Grezes, 2006). Empathy is usually conceived of as simulating other people's experiences, whereas sympathy requires an extra step of feeling for the other person (de Vignemont and Singer, 2006). The frontopolar cortex was activated most consistently for compassion versus a neutral control condition (Immordino-Yang et al., 2009), as well as compared with other-critical feelings (Moll et al., 2007) and compared with self-directed anger (Kedia et al., 2008). None of these studies investigated individual differences in the experience of pity and this may have led to a failure in detecting septal or subgenual cingulate regions engaged by empathic concern while feeling guilt (Zahn et al., 2009a). Interestingly, a study in adolescents and adults found septal/subgenual cingulate activations to be associated with how wrong people perceived depicted immoral actions, but their empathic sadness was associated with paracingulate cortex activation instead, among other regions (Decety et al., 2012).

Other-Critical (other-Blaming) Moral Sentiments

Moral disgust (highly associated with contempt in the authors' pilot studies) and moral anger (highly associated with indignation) are important to motivate altruistic punishment, which is of immense evolutionary importance as discussed. The most reproducibly activated region for these feelings is the lateral orbitofrontal cortex (other-critical vs prosocial moral sentiments (Moll et al., 2007); indignation/anger when being the victim of an action vs guilt when being the agent (Zahn et al., 2009c)). It remains unclear, however, whether regions within the lateral orbitofrontal cortex are selectively involved in other-critical feelings. This is because one study found moral disgust to activate this region more strongly than nonmoral disgust (Moll et al., 2005a), whereas another study found the lateral orbitofrontal cortex activated for both moral and nonmoral disgust compared with a neutral condition (Borg et al., 2008). Another study did report the frontopolar cortex for anger toward others when compared with anger toward self, but there was no comparison with prosocial moral sentiments to directly relate the results to the studies above (Kedia et al., 2008). Loss of anger and disgust were selectively associated with neurodegeneration of posterior dorsomedial prefrontal, dorsal anterior cingulate, and amygdala, when controlling for performance on pity, guilt, and embarrassment (Moll et al., 2011).

While the above studies tested the neural correlate of the subjective experience of specific moral sentiments, another approach has been to probe altruistic decisions compared with selfish decisions. If moral sentiments play a role in motivating these decisions, then one should find partly overlapping areas of brain activation.

Moral versus Selfish Decisions

Figure 2 describes how people were asked to donate to charitable organizations while being in the fMRI scanner (Moll et al., 2006). They were presented with different payoffs for the organization and for themselves and could choose whether they wanted to accept the payoff or not. This allowed the identification of specific neural signatures within the septal-subgenual cingulate region of deciding to donate to charity compared with keeping money for oneself. The frontopolar and anterior orbitofrontal cortex were associated with sacrificing one's money to either donate or punish an organization (i.e., costly decisions). Both monetary rewards and donation decisions were associated with ventral striatum activations. Interestingly, the lateral orbitofrontal cortex was associated with punishing organizations people disliked (e.g., the US National Rifle Association). The septal part of the nucleus accumbens, which is its medial aspect and often overlooked in imaging studies by describing this as ventral striatum activation, was subsequently detected for donation decisions in two fMRI studies (Hsu et al., 2008; Harbaugh et al., 2007). The subgenual cingulate region was also found to be more active in people with higher empathic concern while they made decisions to sacrifice some of their money to help others to avoid an electroshock (Feldman Hall et al., 2012).

Affiliative Motivational States

One basic ingredient for empathic moral sentiments such as pity, guilt, as well as moral decisions based on these feelings is the ability to feel attached to other people (Moll et al., 2008; Moll and Schulkin, 2009). Social attachment such as pair bonding and mother–offspring bonding has been linked to subcortical structures in nonhuman animals (Insel and Young, 2001; Stack et al., 2002). The core subcortical areas implicated in social attachment in nonhuman animals include the preoptic-anterior hypothalamic area, septal region, amygdala, ventral striatum, and the bed nucleus of stria terminalis (Stack et al., 2002). These regions are rich in neuropeptide and monoaminergic receptors (oxytocin, vasopressin, dopamine, and opioid) that have been shown to influence attachment-related behaviors. Human fMRI studies on maternal and romantic love found activation of these key subcortical regions (Bartels and Zeki, 2004; Aron et al., 2005; Swain et al., 2007). A recent study confirmed the prediction that there are regions selectively involved in affiliative emotional/motivational states within the hypothalamic-septal region irrespective of positive or negative emotional valence and irrespective of the context of agency (Moll et al., 2012). This is in keeping with the fronto-temporo-subcortical integration model of moral motivation as arising from decontextualized (i.e., free floating) motivational states in subcortical areas that are bound together with conceptual and sequential action information in anterior temporal and frontal areas to produce the complex experience of moral sentiments and

Figure 2 Brain regions activated when participants donated or were opposed to donate to charitable organizations during fMRI (Moll et al., 2006; figure adapted from Moll, J., Schulkin, J., 2009. Social attachment and aversion in human moral cognition. Neuroscience and Biobehavioral Reviews 33, 456–465). (a) Both pure monetary rewards and decisions to donate (with or without personal financial costs) activated the mesolimbic reward system, including the ventral tegmental area (VTA) and the ventral and dorsal striatum. (b) The septal-subgenual region (SG), however, was selectively activated by decisions to donate, as compared with pure monetary rewards (both by costly and noncostly decisions, conjunction analysis). The lateral orbitofrontal cortex (latOFC) was activated by decisions to oppose charities. This activation extended to the anterior insula and to the inferior dorsolateral prefrontal cortex (PFC) and was present both for costly and noncostly decisions (conjunction analysis). The frontopolar cortex (FPC) and ventral medial PFC (mPFC) were activated for costly decisions (when voluntarily sacrificing one's own money either to donate to a charity or to oppose it (conjunction analysis).

motivations (which always entail a goal rather than just the free-floating motivational state, see **Figure 4**).

Moral Values

Moral sentiments are often tied to abstract values described by social concepts such as 'honesty.' They thereby form moral values, which motivate behavior in a more stable way than the context-dependent rules about certain types of behaviors we feel guilty or proud of in particular situations. The right superior anterior temporal lobe was shown to be equally activated irrespective of the type of moral sentiment (guilt, pride, gratitude, and indignation) associated with sociomoral values, whereas different frontal-subcortical regions were associated with the different moral sentiments (**Figure 3**, (Zahn et al., 2009c)). This provides a neural architecture that allows social conceptual knowledge to be integrated with moral sentiments to give rise to the experience of moral values and thereby motivate behavior.

Process-Based Subdivisions

Frontopolar and anterior dorsolateral prefrontal cortices were consistently found for moral judgment/reasoning tasks (Greene et al., 2004, 2001; Moll et al., 2001). It is unclear, however, whether these activations were selective for moral relative to nonmoral judgment (as compared, for example, in (Moll et al., 2001)), because moral judgments were carried out on moral contents and nonmoral judgments on nonmoral contents, thus confounding process and content. In other approaches to moral judgments, different types of moral dilemmata were compared that differed in contents and were designed to probe different types of processes (Greene et al., 2004, 2001), but again confounding contents with process. The different theoretical interpretations of these findings will be briefly discussed in Section Cognitive-Anatomical Models of Moral Cognition and Emotion. These data do not, however, allow the conclusion that moral reasoning as a process has a specific neuroanatomical substrate.

Other investigators have sought to identify differences in implicit and explicit (Harenski and Hamann, 2006) moral cognition or real versus imagined moral decisions (Feldman Hall et al., 2012). While these may undoubtedly exist, these studies did not investigate whether the difference between these types of processing were selective for moral or social processing, which is the focus of this article.

Cognitive-Anatomical Models of Moral Cognition and Emotion

Anterior dorsolateral prefrontal and frontopolar cortex were found to be activated in moral judgment tasks (Greene et al., 2004, 2001; Moll et al., 2001), but as discussed, there is no evidence for their selective involvement in moral versus nonmoral judgment. The frontopolar cortex does show selectivity for guilt compared with other-critical feelings

Figure 3 Using fMRI in healthy participants this study investigated the neuroanatomical basis of abstract moral and social values (figure adapted from Zahn, R., Moll, J., Paiva, M.M.F., Garrido, G., Krueger, F., Huey, E.D., Grafman, J., 2009c. The neural basis of human social values: evidence from functional MRI. Cerebral Cortex 19, 276–283; Zahn, R., Oliveira-Souza, R., Moll, J., 2011. The neuroscience of moral cognition and emotion. In: Decety, J., Cacioppo, J. (Eds.), The Handbook of Social Neuroscience. Oxford University Press). Participants had to imagine actions in accordance with or counter to a value described by a written sentence and to decide whether they would feel pleasantly or unpleasantly about the action. After the scan, they rated the unpleasantness/pleasantness on a scale and chose labels that best described their feelings (the analysis compares each moral sentiment vs visual fixation and vs two other moral sentiments; only selective effects were reported). There were four experimental conditions: (1) positive self-agency: "Tom (first name of participant) acts generously toward Sam (first name of best friend)" – pride in this condition was associated with ventral tegmental, septal, and ventral medial FPC activation (not depicted); (2) positive other-agency: "Sam acts generously toward Tom" – gratitude in this condition was associated with hypothalamic activation; (3) negative self-agency: "Tom acts stingily toward Sam" – guilt in this condition was associated with subgenual cingulate cortex as well as ventral medial FPC activation (not depicted and only when modeling individual frequency of guilt trials); and (4) negative other-agency: "Sam acts stingily toward Tom" – indignation/anger in this condition was associated with lateral orbitofrontal/insular activation. In the center, one can see the right superior anterior temporal lobe (aTL) region showing equally strong activation during all moral sentiment and agency contexts; this region showed increased activity with increasing richness of conceptual details describing social behavior and is identical to the activation found in a semantic judgment task (Zahn et al., 2007). These results confirmed the right superior anterior temporal lobe as a context-independent store of social conceptual knowledge that allows us to understand the core meaning of social and moral values regardless of what exact feelings or actions one ties to the value.

(see above) and was also activated for affiliative versus nonaffiliative feelings (Moll et al., 2012). It is therefore unlikely to be involved in the process of judgment itself. Unpublished secondary data analyses show that frontopolar activations in the latter study were associated with the number of consequences people thought about during scanning as based on postscanning ratings. This confirms the prediction of the fronto-temporo-subcortical integration model that frontopolar activations contribute to moral cognition by representing consequences of one's actions (**Figure 4**), a crucial ingredient of affiliative moral sentiments (i.e., guilt and pity).

It remains controversial how to interpret frontal activations in moral cognition and emotion; the different models are briefly summarized in **Table 1**. Further details of the fronto-temporo-subcortical integration model of moral cognition and emotion are found in **Figure 4**. This model currently provides the most parsimonious explanation for different cortical activation patterns for different types of moral sentiments (guilt vs indignation). Furthermore, it is so far the only model predicting subcortical and cortical structures with selective involvement in moral motivations. This is consistent with the evidence presented in previous sections. The authors have provided a more detailed discussion of how different models explain the evidence regarding moral dilemma choice paradigms elsewhere (Moll et al., 2008).

Implications for Differential Vulnerability in Psychiatry

The application of moral neuroscience to the study of psychiatric disorders is still in its infancy. It is likely, however, that moral neuroscience will play an important role in understanding differential vulnerability to certain psychiatric disorders. Here, the authors will focus on major depressive disorder (MDD), especially, its melancholic subtype, on the hypermoral, and psychopathy on the hypomoral end of a putative spectrum. This is a highly speculative perspective, but may prove fruitful for designing future experiments to probe this further.

Psychopathy has been long conceived of as a disorder of moral motivation with a lack of guilt and pity while leaving the ability to manipulate others for one's selfish needs intact (Cleckley, 1976). Callousness in patients with psychopathy (Hare, 2003) was indeed found to be associated with gray matter volume reduction in a network of brain regions including the frontopolar and subgenual cortex (de Oliveira-Souza et al., 2008). The anterior subgenual cortex was also found to be less activated in response to moral violation-depicting pictures in incarcerated people with psychopathy compared with a control group (Harenski and Hamann, 2006). The right anterior temporal lobe was another area of abnormal activation in this study and showed gray matter volume loss in a further study in people with psychopathy

Figure 4 Brain regions involved in moral functions based on evidence from brain lesions and functional neuroimaging (adapted from Zahn, R., Oliveira-Souza, R., Moll, J., 2011. The neuroscience of moral cognition and emotion. In: Decety, J., Cacioppo, J. (Eds.), The Handbook of Social Neuroscience. Oxford University Press; Moll, J., and Schulkin, J., 2009. Social attachment and aversion in human moral cognition. Neuroscience and Biobehavioral Reviews 33, 456–465; Moll, J., Zahn, R., de Oliveira-Souza, R., Krueger, F., Grafman, J., 2005b. Opinion: the neural basis of human moral cognition. Nature Reviews Neuroscience 6, 799–809). Cortical region: frontopolar cortex (FPC), medial and lateral ventral prefrontal cortex (PFC), right anterior dorsolateral PFC, anterior temporal lobes (aTL), and posterior superior temporal sulcus (pSTS). Subcortical structures include the extended amygdala, hypothalamus, basal forebrain (especially the preoptic and septal regions), basal ganglia, and midbrain regions. Integration across these corticolimbic structures gives rise to event-feature-emotion complexes (EFEC) by temporal binding according to the fronto-temporo-mesolimbic integration model (Moll et al., 2005b). The hypothesized cognitive-anatomical components are the following: (1) sequential knowledge of actions/events represented within PFC subregions. FPC: complex branching of consequences of actions and ventral PFC regions representing associative knowledge of motivational/emotional states embedded into sequential event/action contexts; (2) social sensory features stored in pSTS and abstract (i.e., context-independent) conceptual knowledge of social behavior stored in the anterior temporal cortex, especially in the superior sectors; (3) central motive or basic emotional states, such as 'free-floating' anger, attachment, sadness, and sexual arousal (represented by the subcortical structures listed earlier).

Table 1 Alternative models of the role of frontal cortex in social and moral behavior

Hypothesis label	*Main claim*
Top-down frontal cognitive control	Frontal cortex does not store linkages between stimulus and response, but it represents goals that control the information flow in other cortical and subcortical areas when an automatic response needs to be overcome (Miller and Cohen, 2001).
Bottom–up subcortical control	Ventral (medial) frontal cortex stores linkages of subcortical 'somatic markers' and action knowledge in posterior brain areas. Explains problems with rapid and complex decision making after ventral (medial) frontal lesions (Bechara et al., 2000).
Reciprocal fronto-temporo-subcortical integration	Context-dependent knowledge of sequences of social actions/events is stored in ventral frontal (and frontopolar) cortex necessary to enable context-appropriate social behavior (Moll et al., 2005b). In this model, the frontal cortex stores sequential information linking stimuli and responses in different contexts.

Three alternative models of frontal involvement in social and moral cognition are summarized. The influential cognitive control model has subsequently been extended to the moral domain as the dual-process model of moral cognition and emotion (Greene et al., 2004). The assumption of this model is that 'rational' or 'cognitive' processes relying on dorsolateral prefrontal and parietal cortex can be separated anatomically from 'emotional' processes relying on subcortical and ventromedial frontal areas. Therefore, the model predicts that rational and emotional processing of moral dilemmata leads to different choices. The authors have pointed out that the model fails to explain how different types of emotions (e.g., guilt and indignation) and different types of motivations (e.g., selfish vs moral) can be accounted for. The reciprocal fronto-temporo-subcortical integration model of moral cognition and emotion is based on representations of different types of contents within each brain area of the network. This allows for explaining dissociations between different types of contents relying on different parts of one larger brain area (Moll et al., 2008).

(Muller et al., 2008). Frontopolar and anterior temporal lobe gray matter volume loss were reproduced as the distinctive feature of people with psychopathy compared with people with antisocial personality disorder, but no psychopathy (Gregory et al., 2012). The right uncinate fascicle, a white matter tract connecting temporal poles, ventral frontal cortices, and subcortical structures, was found to show decreased structural connectivity in people with psychopathy (Eslinger et al., 2004), which may be a result of the cortical changes described above or vice versa.

MDD is associated with overgeneral forms of empathy-based interpersonal guilt (e.g., 'feeling responsible for everything,' (O'Connor et al., 2002)), which remained detectable on remission of symptoms in a group of primarily melancholic subtype patients (Green et al., 2013) suggesting this as a trait vulnerability factor. One hypothesis is that increased guilt proneness in MDD may have an influence on helping behavior outside of depressive episodes (O'Connor et al., 2002). This link has so far, however, not been conclusively demonstrated and the overgeneral and uncontrollable nature of self-blame as proposed in an influential cognitive model of MDD (Abramson et al., 1978) could lead to the opposite prediction of a propensity to withdraw from helping others (Tangney et al., 2007). Overgeneralization of guilt (i.e., feeling guilty for everything and thus hating oneself as a result) was associated with functional disconnection of the right superior anterior temporal lobe and the septal-subgenual cingulate region in people with MDD whose symptoms had subsided (Green et al., 2012). This functional disconnection was only present for guilt and not for indignation, thus confirming the selectivity for overgeneral self-blame, explaining the relatively infrequent occurrence of violence in people with pure major depression (Green et al., 2013). This confirmed the prediction of frontotemporal integration as critical for adaptive moral motivations (Moll et al., 2005b). Further studies of neural correlates of moral sentiments in affective disorders are needed to confirm and extend these findings.

Conclusions and Future Directions

The authors have presented evidence that the septal-subgenual cingulate and septohypothalamic area are currently the best candidates for hosting subregions with selective involvement in moral versus selfish motivations. The authors have further reviewed the reproducible involvement of the frontopolar cortex for prosocial moral sentiments relative to other-critical sentiments. None of the other brain areas activated in moral cognition and emotion tasks were yet shown to be credible candidates for selective involvement in moral relative to nonmoral motivations. Social knowledge as a critical prerequisite of moral cognition and emotion is only partly understood in that its context-independent (i.e., conceptual) aspects can be localized within the right anterior temporal lobe. Future studies are needed to confirm these findings and to extend the understanding of the functional contribution of different frontal brain regions. An exciting future of applying these new insights to an improved pathophysiological understanding and treatment of psychiatric disorders lies ahead.

Neural Plasticity

Abstract

Once it was thought that the human brain is immutable; but now it transpires that neural systems in human brains are highly plastic because the brain circuits are not fully specified by the genes. They are plastic in the sense that they are capable of changing in form and function in response to changes in the environment or damage to neural systems. Normal and altered brain development, learning and imprinting, and recoveries from brain injury and sensory loss all depend on this capacity, which is mediated by the growth and formation of new neural connections in the brain. Neural plasticity is provoked by genetic and cellular responses to changes in neural activity patterns.

Neural plasticity refers to the ability of neurons and neuron circuits to change in form and function in response to alterations in their environment. Neurons function as parts of local circuits in the brain, and each neuron can change its functional role in a circuit by altering how it responds to inputs or influences other neurons. Neuronal interactions for computational functions largely depend on synaptic relationships, and neural plasticity largely results from changes in the strengths of synaptic connections between neurons and the formation of new connections. Neural plasticity occurs as neurons respond to the activities of neighboring neurons that are spontaneously active or are activated by events in the external environment, and to trophic and guidance factors released in the local environment. Neural plasticity is essential for the normal development of brain circuits, creating the differences in those circuits that make us individuals. Neural plasticity mediates the acquisition of knowledge and skill, and brain repair after injury. Plasticity may also lead to misperceptions and pain, and maladaptive behavior. An understanding of neural plasticity might help us promote this plasticity when it is useful, and control this plasticity when it has unfortunate consequences.

Neural Plasticity during Brain Development

The basic circuitry of the brain gradually emerges during development. While the mature brain remains plastic, developmental changes are especially impressive. For example, a short period of sensory loss, such as produced by having an eye covered by a patch early in childhood, can have a devastating effect on vision of that eye. The brain circuits for vision become dominated by the unpatched seeing eye so that connections and synaptic strengths change, deprived neurons fail to grow and axon branches withdraw, and a deficit in vision for the closed eye occurs that persists even after the removal of the eye patch (Antonini and Stryker, 1993). A similar period of deprivation in adults has little effect. The developing brain is especially plastic because it is using information from the environment to help construct itself (Rauschecker, 1991; Schatz, 1990). Slight changes in the instructions from the environment, and the timing of those instructions can lead to quite different outcomes. In the mature brain, the circuits have been built, and further modifications are usually less profound.

One of the important accomplishments of developmental plasticity is to create functionally adaptive circuits in the brain. Developmental plasticity refers to the capacity of the brain to have different developmental outcomes. The development of some brain circuits, some of those in simple invertebrates, for example, may be highly fixed. Thus, the developing circuits usually achieve the same adult form. But, this is not necessarily the case for the complex circuits of the higher brain centers of mammals, especially those in humans with long periods of development. The human brain is highly plastic because the brain circuits are not fully specified by the genes. All of the necessary information for proper development does not reside in the genes or gene products. Thus, it is necessary to use information from the environment to direct development. Neurons are designed to respond to sensory stimuli and each other with action potentials or spikes. Self-generated spontaneous activity and evoked activity are very important in mediating normal development (Schatz, 1990). Neurons also influence the development of other neurons through the release of trophic and guidance factors (Conner and Dragunow, 1998).

Consistencies in the internal and external environments during development typically lead to the development of similar brains with very similar brain circuits. Because the developmental outcomes can be so similar, the role of the environment may not always be obvious. Thus, one way to study developmental plasticity is to rear animals in abnormal environments (Rauschecker, 1991). As examples, the development of the visual system can be altered by rearing mammals in the dark, with one eye closed, or under strobe lights. These experiments indicate that sensitivity to the environment is an important component of the normal development of brain circuits. In an abnormal environment, development can be misdirected, often with unfortunate functional consequences.

Sensitivity to the environment also allows the developing nervous system to become tailored to specifics of the environment of the individual. The newly hatched bird imprints on its parents, rather than birds in general, although even a moving box or balloon will do in the absence of tending parents. The young bird can become completely attached to such obviously false parents. The child that practices piano or basketball becomes the great piano or basketball player. Humans learn the sounds of their own language, and as adults

find it hard to process the sounds of other languages. Thus, neural plasticity allows the brain to adapt to an uncertain environment, and permits specializing the formation of neural circuits within individuals for individual needs.

Because neuronal circuits are designed to be altered by aspects of the environment at certain times in development, or subsequently during critical points – a period in brain development when certain brain circuits are highly capable of modification as a result of experience – in the lifecycle, there are changes in circuits that are possible only at certain times, and these changes are often difficult or impossible to reverse. These times are called critical or sensitive periods. Eye patching for a period of days to weeks, for example, will greatly alter brain circuits, only during a fixed early period of visual development. Earlier or later periods of deprivation have little effect. There may be a critical or sensitive period for songbirds learning songs, for human language to be easily and flawlessly acquired, and for learning perfect pitch.

In summary, neural plasticity is essential for normal brain development, especially for the development of large complex brains that mature slowly. The normal development of the human brain is especially dependent on neuronal plasticity. Many circuits require information from the environment in order to develop properly. In addition, neuronal plasticity allows the development of the individual differences, including individual skills and abilities.

Neural Plasticity and the Lifecycle

Neural plasticity also allows brain circuits to function differently at different phases of the lifecycle. Hormones play a major role in adjusting neural circuits. Songbirds, for example, adjust and even add new neurons to the neural circuits used in producing and acquiring songs used during the breeding season (Konishi, 1985). At puberty, humans and other mammals alter brain circuits that mediate aspects of sexual behavior, and later brain circuits are adjusted to promote maternal and paternal behaviors. Thus, plasticity permits rapid and functionally important changes in brain circuits as life styles change with puberty and parenthood.

Neural Plasticity and Learning

Learning is based on neural plasticity. Each individual acquires a great deal of useful information about the environment through experience, and improves and perfects a great number of motor skills. The importance of learning varies with species, and it is probably most important in humans. There are several types of learning, but they all depend on modifying the functional circuits of neurons.

The neuronal mechanisms of learning are not fully understood, although they have been under intensive study for many years. It is likely that two types of induced changes in synaptic effectiveness between neurons are important in most learning situations. When a source of input to a neuron or group of neurons is intensely stimulated for a brief period of time, subsequent stimulations might be more effective and produce a greater response. This change in synaptic effectiveness, which may persist for minutes to hours or longer, has been called long-term potentiation (LTP; see Bliss and Lomo, 1973). Of course, new learning involves forgetting, so that connection strengths need to be weakened as well. Patterns of less intense, more distributed stimulation may reduce synaptic effectiveness. This reduction is called long-term depression (LTD; see Nelson and Turringiano, 1998). Possibly, LTP depends on reversing LTD.

Both LTP and LTD are likely to be critical components of memory formation and the acquisition of skills. LTP and LTD have been most studied in the hippocampus, both in a tissue slice preparation, which offers clear technical advantages, and in the intact animal. LTP and LTD are components of what has been called Hebbian plasticity (see Brown et al., 1988; Rauschecker, 1991) after the neuropsychologist, Donald Hebb. In an effort to account for learning, Hebb theorized that the repeated activations of local neuron circuits changed the effectiveness of pathways so that some inputs came to activate the circuits more easily and more effectively. If neuron A takes part in the firing of neuron B, the future effectiveness of neuron A in firing neuron B is increased. The cellular mechanisms of Hebbian plasticity have been studied, and they involve the activation of the NMDA (N-methyl-D-aspartate) glutamate receptor and a calcium influx into the postsynaptic neuron when presynaptic activity is paired with postsynaptic depolarization (Bear, 1995; Rauschecker, 1991). The hippocampus is known to have a critical early role in the formation of long-term memories, but it is not generally thought to be the site of permanent storage. The amygdala encodes the emotional component of memories formed during fear conditioning, but like the hippocampus, the neuronal plasticity that occurs in the amygdala may modulate the consolidation of memories formed elsewhere.

Most memories and skills depend on neocortex. LTP and LTD also have been demonstrated in neocortex circuits where these types of synaptic plasticity are likely to be important in the consolidation and storage of information. Finally, plastic circuits in the basal ganglia are used in the acquisition of motor skills (Graybiel, 1995).

Neural Plasticity and Brain Repair

Neural plasticity is also important in brain reorganization and repair after injury. The effects of sensory loss have been extensively studied in the sensory systems of adult mammals (Kaas, 2001; Kaas et al., 2008). Sensory loss of one type or another commonly occurs during adult life. For example, humans typically lose auditory receptors and, especially, high-frequency hearing as they age. Studies in monkeys, cats, and rodents show that auditory cortex reorganizes after such partial hearing loss so that more neurons are devoted to processing the remaining inputs. The functional significance of this reorganization is not clear, but it may help individuals adjust to the hearing loss and more effectively use the remaining inputs. Similar changes occur when small portions of the retina are damaged. The regions of visual cortex that are deprived of their normal sources of activation by such damage soon come to be responsive to surrounding intact parts of the retina.

Finally, any restricted loss of tactile inputs from the skin, such as those caused by nerve damage, is followed by a

reorganization of somatosensory cortex so that deprived neurons become responsive to preserved tactile afferents. Such findings indicate that the brains of even adult mammals have considerable capacity for functional reorganization so that neurons that are deprived of a normal source of activation gradually acquire new sources of activation. Unresponsive neurons are not of much use, and the reactivation of deprived neurons, as a common feature of brain damage, may greatly contribute to behavior recovery and compensation. The mature brain may well be designed to compensate for some neuronal loss and damage, and reorganization may lead to more effective use of remaining neurons and neural circuits. Humans and other mammals compensate remarkably well from cortical damage that is relatively restricted. In part, this may be the result of reorganization within the damaged area of cortex. Sensory and motor representations in cortex reorganize after damage to recover some of the lost parts of the representation. Other intact areas of cortex may reorganize to help compensate for the loss. During some periods of brain development, some parts of the brain may be capable of regenerating lost neurons (Kolb et al., 1998). Impressive recoveries after brain damage may reflect design features involving plasticity, or even the fortunate utilization of mechanisms built in by selection for normal development and adult learning. However, plasticity is not always beneficial. The plasticity that is there for one set of purposes may be evoked in other sets of circumstances where the results are detrimental and unfortunate. As one example, individuals with amputated limbs typically feel that the missing limb is still there (Ramachandran and Blakeslee, 1998). This may be the result of neurons in the brain, deprived of normal sources of activation by afferents from the missing limb, becoming more sensitive to intrinsic signals or other inputs. The growth of new connections in the brainstem and cortex seems to add the further complexity of trigger zones, locations on the face and stump that, if touched, evoke a sensation in the missing limb. Fortunately, this type of misperception is not very disturbing. However, severe pain also might be felt in the missing limb, apparently as a result of the plasticity of circuits in the thalamus. This pain is very difficult to treat as it is not generated in the normal way. As another example of maladaptive plasticity, individuals that over practice a skill may develop motor disorders or dystonias (Bly et al., 1996). Neural plasticity is essential for developing motor skills, but musicians and writers may over practice or overuse a skill so that performance deteriorates rather than improves. The practice may coactivate neurons so frequently that they become so strongly interconnected that they fail to respond independently when needed in other neuronal circuits. Thus, the musician loses control of the skilled hand movements needed to play, and the writer develops writer's cramp. Recoveries depend on other training and experiences that rebalance the motor circuits.

Mechanisms of Neural Plasticity

Brain circuits are plastic because new connections form, unused connections are lost, and existing connections increase or decrease in effectiveness. Developing brains are especially plastic because it is a time of great neuronal growth. Activity-dependent genes (Kaczmarek and Chaudhuri, 1997) within neurons function to promote and direct new growth, or stop growth, and cause retractions of axons and dendrites and even cell death. The developing nervous system overproduces neurons and connections, and uses activity patterns induced in neurons by the external and internal environments to select the useful, more active neurons and connections and eliminate other less active neurons and connections. By altering activity patterns through lesions, drugs, and experience, outcomes can be changed so that normally lost neurons are saved, normally lost connections are preserved, and even new growth occurs. One of the early discoveries was that rats reared in a complex rather than a simple environment (Greenough et al., 1985) developed a thicker cortex with larger neurons and more complex dendritic arbors. As a more unusual, more dramatic, example of developmental plasticity, rodents reared after a major loss of auditory inputs to the forebrain grow visual inputs into the auditory thalamus, so that auditory cortex is activated by visual stimuli (Sur et al., 1988). The potential for the growth as well as the loss of new connections is great in the developing brain. Neuronal growth and death can be a feature of normal lifestyle changes as well. Neurons may increase in size and connectional complexity in brain regions related to sexual behavior or bird song during appropriate parts of the breeding season, and then shrink and disconnect subsequently (Konishi, 1985). Neurons may even be born and added to such circuits, to subsequently die. While neuronal growth and even death are major components of programmed plasticity for expected developmental and lifecycle events, much less new growth or retraction might be expected at other times in the mature brain, which has developed brain circuits for a period of stable performance. Indeed, except for learning and learning mechanisms, the mature brain has been considered to be rather fixed in organization and not plastic. Now, considerable evidence has accumulated to show that the functional organization of the mature brain is quite mutable (Kaas, 2001), and that at least some of the changes depend on the growth of new connections, including dendritic branches and spines, and axonal sprouting (Darian-Smith, 2009). In cases of severe sensory loss, such as with brain or spinal cord lesions, or peripheral nerve damage, growth of axons over considerable distances occurs to reactivate deprived neurons in the spinal cord, brainstem, and cortex. While extensive new growth in the mature brain is often likely to be detrimental, and glial cells in the central nervous system produce factors that inhibit such new growth, the local growth of axons and dendrites is probably ongoing and common. In addition, the cellular factors for inhibiting more extensive growth may be overcome by extreme deprivation. It remains to be demonstrated how much new growth contributes to behavioral recoveries after brain damage, but a major contribution by new growth seems likely. In addition, new neurons may be added to injured and disconnected parts of the brain throughout life (Darian-Smith, 2009). While neurogenesis had been thought to be limited to the period of brain development, recent evidence for the addition of neurons to the mature primate brain raises the possibility

that such new neurons contribute to brain plasticity. A common and possibly more powerful factor in neural plasticity is increasing or decreasing the effectiveness of existing connections. This can be done by increasing or decreasing the number, sizes, and positions of synapses, the amount of neurotransmitter released, and the receptor sites responsive to the transmitter. The important roles of LTP and LTD have already been discussed. These mechanisms may be potentiated by the appropriate release of neuromodulators that increase neural activity for short but behaviorally significant periods of time. Thus, stressful and other motivating events activate brainstem neurons that release the neurotransmitter, acetylcholine (ACh) throughout the brain where synaptic strengths are likely to be modified. This makes the changes in neural circuits more likely, so that the motivating events can be retained in memory and skills can be acquired more readily. The permissive effects of ACh release on neural plasticity can even be obtained artificially by electrically stimulating the brainstem neurons that project to cortex and release ACh during learning (Kilgard and Merzenich, 1998).

There are many other ways of promoting neural plasticity. Neurons tend to self-regulate through the actions of activity-dependent genes to reach a set level of activity. Neurons with lowered levels of activity tend to express lower levels of the inhibitory neurotransmitter, gamma-aminobutyric acid (GABA), or become less sensitive to GABA by making fewer GABA receptors (Hendry and Jones, 1988). More active neurons make more GABA and more GABA receptors. Thus, deprived neurons become more sensitive and respond to inputs that were previously subthreshold and ineffective, while overactive neurons lose responsiveness to weak but previously effective inputs. Other activity-dependent genes probably regulate neuron growth through the release of trophic and guidance factors. In addition, it is possible to selectively promote the formation of new connections in the brain by temporarily digesting the perineuronal nets that form to inhibit the growth of new connections as the nervous system matures (Bowes et al., 2012). Thus, there are treatments that can be used to facilitate recoveries from sensory loss and damage to the brain.

Conclusions

Neural plasticity is important for the normal development and maintenance of neural circuits. This plasticity adjusts mature brain circuits to mediate individual perceptual and motor skills, and adaptive adjustments to an uncertain environment. Neural plasticity is especially important in storing information. Plasticity also functions in brain repair. Because some outcomes of neuronal plasticity are highly desirable, while others are unfortunate, a comprehensive understanding of the mechanisms of plasticity and how to control them would be clinically and therapeutically beneficial.

Neural Representations of Direction (Head Direction Cells)

Jeffrey S Taube, Dartmouth College, Hanover, NH, USA

Abstract

To navigate successfully animals require knowledge about their location and directional orientation before embarking on a route. Cells in several limbic-system brain areas discharge in relation to the animal's directional heading in the azimuthal plane independent of location and are referred to as head direction (HD) cells. Each HD cell is tuned to a particular direction, which can be controlled by a visual landmark. However, directional firing is maintained in the absence of visual landmarks by using idiothetic cues, suggesting that the cell's response represents the animal's perceived directional heading. The vestibular system is critical for generating the directional signal.

The Head Direction Signal

To navigate successfully animals require knowledge about their location and directional heading before embarking on a route. While location information may be provided by place cells in the hippocampus, which discharge with respect to the animal's location, or grid cells in the entorhinal cortex, which discharge in a repeating tessellated hexagonal pattern (*see* Human Spatial Orientation, Neural Basis of), another group of limbic system neurons discharge in relation to the animal's directional heading in the azimuthal plane, independent of the animal's behavior and location (Taube et al., 1990a; Wiener and Taube, 2005; Taube, 2007). For example, a head direction (HD) cell might discharge whenever the animal points its head northeast, no matter where it is in the environment. The direction at which the cell fires maximally is referred to as the preferred firing direction. The position of the animal's trunk does not affect the cell's firing, nor does pitch or roll of the animal's head up to 90°. HD cell firing is motion-independent – cells will discharge whether the rat is moving or remains still, as long as the animal is pointing its head in the proper direction. Very little, if any, adaptation of firing rate is noted when the head remains fixed at the preferred firing direction.

HD cells are tuned to different directional headings, and within a particular brain area the cell population collectively encodes all 360° directions. Each HD cell can be characterized by its tuning curve, constructed by plotting firing rate as a function of directional heading. **Figure 1** shows a typical tuning curve for an HD cell that fired maximally at ~150. For each HD cell several properties can be characterized from its tuning curve: (1) the cell's preferred firing direction; (2) the maximal (peak) firing rate of the cell at the preferred direction; and (3) the angular range over which cell firing is elevated from background firing rate. Some HD cells have low peak firing rates (5–10 spikes per second) while other HD cells have high peak firing rates (100 spikes per second). Intermediate peak firing rates are also observed. The functional significance of different cells having different peak firing rates is unknown. The firing rate of each HD cell decreases linearly as one moves away from the preferred firing direction. The range of directional headings where firing is elevated above background firing levels is about 90° for most cells. The firing characteristics of an HD cell usually remain stable indefinitely, as long as the environmental parameters remain unchanged. Passive rotation of a head-fixed animal in the horizontal plane does not lead to any significant changes in cell firing properties, indicating that active head movements per se are not necessary to drive cell firing (Shinder and Taube, 2011).

Figure 1 Firing rate versus head direction plot for a typical HD cell.

Where Are HD Cells Located in the Brain?

HD cells were originally identified in the dorsal portion of the presubiculum in rats (often referred to as the postsubiculum) by James Ranck. They have subsequently been identified in several limbic system areas in the rat, including the anterior dorsal, anterior ventral, and lateral dorsal thalamic nuclei, lateral mammillary nuclei, parasubiculum, and retrosplenial and medial entorhinal cortices (Taube, 2007). Note that many of these areas are considered part of the classical Papez circuit (**Figure 2**). HD cells have also been identified in some nonlimbic structures such as the dorsal striatum and medial granular cortex in the rodent's frontal cortex. The functional significance of having the signal present in so many different brain areas is presently unclear.

HD cells have been observed in a number of different species: mice, guinea pigs, chinchillas, and nonhuman primates. Importantly, the directional firing in the presubiculum of nonhuman primates has been shown to be independent of eye position, suggesting that the signal

Figure 2 Head direction network.

represents the true directional heading of the animal and not its gaze direction (Robertson et al., 1999). With few exceptions, HD cells in each of the different brain areas have similar tuning curves, and behave similarly following manipulations of the animal's environment. However, HD cells in the anterior dorsal thalamus and lateral mammillary nuclei appear to discharge optimally to the animal's future directional heading, while HD cells in the dorsal presubiculum discharge maximally to the animal's current directional heading (Blair and Sharp, 1995). Similarly, in contrast to HD cells in the dorsal presubiculum, HD cell firing in the anterior dorsal thalamus and lateral mammillary nuclei is secondarily correlated to the rat's angular head velocity (AHV), where firing rates within the cell's preferred direction are higher for faster head turns than slower head turns (Taube, 1995). It is also noteworthy that there are distinct populations of cells in the lateral mammillary nuclei that, independent of directional heading, encode for either pitch of the animal's head or AHV (Stackman and Taube, 1998).

HD Cell Responses in 3D

How HD cells respond when the animal is oriented outside the yaw (Earth horizontal) plane has also been studied during the past decade. HD cells maintain their directional firing properties in the vertical plane, but usually lose them when they are inverted and locomote upside-down on a ceiling (Taube, 2011). When an animal actively locomotes from the horizontal plane into the vertical plane while moving in the direction of the cell's preferred firing direction, the cell will continue to discharge in the vertical plane, but if the vertical plane locomotion begins with the animal's head orientation

outside the cell's preferred direction, then the cell will not discharge on the vertical wall until the animal turns its head to the proper orientation. One model consistent with these findings is that HD cells define the horizontal reference frame as the animal's plane of locomotion, but this leaves open the question of which cue source(s) determine the horizontal reference frame: vestibular, somatosensory, visual, motor cues, or some combination of these sources. Alternatively, HD cells may define their reference frame in a fixed earth-based coordinate system, where their three-dimensional firing characteristics, in terms of yaw and pitch and using polar coordinates, can be represented as the surface of a hemitorus. In contrast to stable directional firing in the vertical plane, if the animal continues to move from the vertical plane onto a ceiling in an inverted (upside-down) position, then directional cell firing will cease. Why directional firing is disrupted when the animal is inverted is unclear, but recent findings have shown that the vestibular otolith organs, which are sensitive to the direction of gravity, play an important role in HD cell firing (Yoder and Taube, 2009).

Both Landmark Cues and Internally Derived Self-Motion Cues Affect HD Cell Firing

While HD cells bear a similarity to a navigational compass, they are not dependent on the Earth's magnetic field. They respond to several different types of sensory stimuli, some of which are external to the animal and others of which are self-generated. Visual landmarks that are stable over time play the predominant role in controlling the HD cell's preferred firing direction. For example, if an animal is first disoriented and then returned to a familiar environment where all the visual landmarks have been rotated, the HD cell's preferred firing direction will also shift a similar amount (Taube et al., 1990b). The postsubiculum plays a critical role in processing visual landmark information as lesions of it will impair the ability of a landmark to control HD cell preferred firing directions and hippocampal place cell fields (Yoder et al., 2011). Interestingly, neither disruption of the dorsal or ventral visual streams, via lesions of the parietal or entorhinal/postrhinal cortices, respectively, impair landmark control of HD cells, suggesting that the direct pathway from visual cortex to postsubiculum may convey information about visual landmarks to the limbic system.

Although visual landmarks exert strong control over their preferred firing directions, HD cells continue to respond normally when the animal moves about in darkness or when the prominent visual cues are removed, indicating that self-motion cues are capable of maintaining directional firing as well as the cell's preferred firing direction. HD cell firing is not environment- or context-specific, and the cells will discharge at some direction in any environment. These characteristics suggest that the HD cell network resembles more a population coding scheme rather than a sparse coding scheme. If an animal locomotes from a familiar to a novel environment, the preferred firing direction will be similar in both environments (Taube and Burton, 1995). These findings indicate that HD cells receive information concerning the animal's movements, either through vestibular, proprioceptive, or motor corollary discharge systems. This movement information is integrated over time so that the animal can keep track of its directional heading given an initial reference point. When an animal is passively transported from a familiar to a novel environment the preferred firing direction of a cell will often shift substantially, indicating the important role that motor systems play in maintaining a stable preferred firing direction (Stackman et al., 2003). Under this condition, the animal is deprived of the normal motor, proprioceptive, and kinesthetic cues that accompany self-locomotion, but vestibular cues are left intact. Thus, while the vestibular system may play a crucial role in the generation of the HD cell signal (see below), these findings indicate that vestibular cues alone are not sufficient to allow maintenance of a stable preferred direction and suggest a critical role for motor information for updating the signal over time.

Most studies have shown that when spatial information derived from landmarks conflicts with information derived from internally generated self-movement, the landmark information usually predominates and overrides the spatial signals developed through self-generated movements. Thus, when a salient, familiar cue is reintroduced into an animal's environment into a position that conflicts with the cell's current preferred firing direction, HD cells will shift their preferred direction to reflect their originally established orientation with the cue.

When two or more HD cells are monitored simultaneously in the same animal, the effects of an environmental manipulation on the preferred direction for one cell are similar to the responses observed in the other cell(s) (Taube et al., 1990b). This finding indicates that afferent input driving one HD cell will similarly influence other HD cells, and indicates that HD cells within a particular brain area behave as a network and that their preferred directions always remain a fixed angle apart (in-register) from one other.

Generation of the Directional Signal

Given that HD cells have been identified in several brain areas, many of which are interconnected with one another, the question arises as to which areas are critical for generating the directional signal. By recording from one brain area containing HD cells, and lesioning various afferent areas, a number of studies have concluded that (1) the vestibular system plays a critical role in generating and updating the directional signal (Stackman and Taube, 1997; Muir et al., 2009), and (2) that there is a general hierarchical flow of information that originates in the vestibular nuclei and then projects rostrally in the following sequence (see **Figure 2**): medial vestibular nuclei → supragenual nuclei and nucleus propositus (and possibly the paragigantocellularis reticular nucleus - not pictured in **Fig. 2**) → dorsal tegmental nuclei → lateral mammillary nuclei → anterodorsal thalamus → postsubiculum → medial entorhinal cortex (Sharp et al., 2001a; Taube, 2007). The importance of the vestibular system for generating the directional signal is also consistent with findings demonstrating the presence of cells sensitive to the animal's AHV throughout many of the brainstem nuclei mentioned above (Bassett and Taube, 2001; Sharp et al., 2001b).

Lesions of the anterior dorsal thalamus or the postsubiculum do not abolish location-specific firing in

hippocampal place cells, indicating that spatial representations concerning location can be generated independently of HD cell information. In contrast, recent evidence suggests that grid cell firing in the entorhinal cortex is dependent on HD signals, as lesions of the anterodorsal thalamus abolish the grid cell signal (Clark et al., 2011). The vestibular lesion data suggest that the neural code for directional bearing is critically dependent upon vestibular information, and that the loss of HD cell information may account for the orientation and navigational deficits observed following vestibular dysfunction in humans. Attempts to model HD cell firing have used attractor-type neural networks. These models have been able to replicate most, but not all, of the empirical data.

In animals with lesions of the hippocampus each HD cell's preferred firing direction remained stable across days, even when the animal was placed into a novel environment post-lesion (Golob and Taube, 1997). This result suggests that extrahippocampal structures are capable of creating and maintaining a novel representation of the animal's spatial context – at least in regards to the animal's directional heading. This association is considered a form of perceptual learning, as opposed to episodic learning.

Relationship of HD Cell Activity to Behavior

One important issue concerning HD cells is what role they play in an animal's behavior (Muir and Taube, 2002). Are HD cells actively involved in guiding navigational behavior? Evidence suggesting a link between HD cells and behavior has been produced using a radial arm maze in a spatial reference memory task. Animals were trained to run down a particular maze arm relative to a visible landmark cue to obtain a water reward. Following rotation of the cue, the animal's maze arm selection and the HD cell's preferred direction shifted in tandem relative to the salient visual cue. Furthermore, when the HD cell's preferred direction did not shift relative to the cue, neither did the animal's behavioral response. When an HD cell was recorded over several days as the animal learned the task, there was little change in the firing properties of the cell. These findings indicate that the coding of directional heading information is independent of the neural systems involved in task acquisition, and that over time, an animal learns to use information provided by the directional system to guide its behavioral responses.

Other experiments that have tested this hypothesis more rigorously have surprisingly found that HD cell activity and behavioral choice were not linked together on two different types of associative spatial tasks. One task was a spatial reference memory task where animals were required to generalize appropriately between a square and a rectangular enclosure to receive a reward. The other task involved a spatial working memory task. In both cases HD cell activity in the anterior dorsal thalamus did not correlate very well with the animal's behavioral responses. Recent experiments have shown that the spatial information from HD cell activity closely matched an animal's response in the food-hoarding task, a task that requires path integration (Valerio and Taube, 2012). In addition, this study found that there were two types of correction processes that occurred when the animals made an error in their homeward path. With small behavioral errors, the cells' preferred directions were reset to their original orientations upon the animal's return to the home base. In contrast, when behavior errors were large (>50°) animals 'remapped' their spatial reference system to the cells' new orientations.

More recent studies have utilized the finding that direction-specific firing is disrupted when the animal is inverted and shown that the presence of the directional signal is necessary if the animal is to perform a spatial task that requires a flexible representation of space (Gibson et al., 2013). Although animals were able to perform a spatial task from an inverted orientation when they were released from one of the two locations, their performance fell to chance when released from a novel location. Simultaneous to these behavioral outcomes, direction-specific firing in HD cells was impaired throughout the task, suggesting that their firing was necessary when a spatial mapping strategy was needed (i.e., cognitive map), but not when the task relied more on a relatively simple beacon or response strategy.

Summary

In summary, HD cells represent a high-level spatial signal that encodes the animal's directional heading. HD cells have been identified in several brain areas – mostly within the limbic system, but the functional role served by each brain area remains to be elucidated. HD cells receive multimodal sensory and motor information. It appears that the signal arises from the lateral mammillary nuclei, or subcortical structures afferent to it, and that both vestibular and motor information play important roles in generating the signal. Visual landmarks can exert control over the preferred firing direction of an HD cell. The nature of the HD cell signal makes it an ideal candidate for studying the neural mechanisms underlying navigation.

Abstract

Large regions of occipito-temporal cortex are recruited during the visual perception of objects. Here we review data from single unit (individual neurons), and neuroimaging studies to consider how objects are encoded in cortex, and the organization of the cortical machinery supporting object perception.

representation, *n.*[1]

> *… Something which stands for or denotes another symbolically; an image, a symbol, a sign. Chiefly with of ….*
>
> Oxford English Dictionary online edition; http://www.oed.edu

Within cognitive science, mental representations are taken to be high-level, manipulable entities that 'stand for' things in the world. More narrowly, in the study of vision, object representations are taken to be *spatial* in that they encode the approximate shape properties of physical objects (Pinker, 1985). In either case, although we (and the field) may have strong intuitions about what we mean by 'representation,' specifying the actual content of mental representations is rather difficult, with even fundamental concepts such as what constitutes a visual 'feature' being severely under-constrained. When discussing the *neural representation* of objects, things become murkier still.

What does it mean to neurally 'represent' a visual object? Can a neural signal emanating from one neuron or millions of neurons ever 'stand for' an object? It is our contention that the neural responses our field refers to as 'object representations' are nothing of the sort. For example, single neuron spikes of 'face cells' do not stand for faces (Tsao et al., 2006) anymore than the summed responses of millions of neurons, as measured indirectly by fMRI, across the 'extrastriate body area' stand for human bodies (Downing et al., 2001). Although others have argued against such results on theoretical grounds – in particular, suggesting that these nominally domain-specific responses are actually part of more domain-general processing systems (Tarr and Gauthier, 2000) – our argument here is a philosophical one: mental constructs cannot be reduced to localized patterns of neural activity. That is, in reviewing how neural structures support object perception and processing, we should always consider experimental results in a context whereby neurons, populations of neurons, and neural systems carry and encode information, but in which this information, in and of itself, is not about/of objects.

How Small Numbers of Neurons (May) Code Information about Objects

One of the most commonly measured units of 'representation' in the brain is the neuron. Somewhat surprisingly, some functional information about objects seems to be coded at this incredibly fine scale. Single-unit recordings of neurons in the ventral visual cortex reveal activity that is often tuned to individual objects or classes of objects. That is, a particular stimulus object presented in the receptive field of a given neuron will produce significantly greater activity (more spikes per second) in that neuron as compared to any other tested stimulus (typically a varied assortment of natural and artifactual objects). For example, neurons in many cortical areas along the ventral pathway – the part of the primate brain that is thought to support high-level vision, including object recognition – are highly selective for object categories that have been previously presented (Sheinberg and Logothetis, 2001). Similarly, cortical neurons may be specifically selective to individual objects within a category, at least when the stimuli are very familiar to the monkey, having been seen hundreds of times previously (Logothetis and Sheinberg, 1996). And lastly, there is extensive evidence that many different regions (or 'patches') along the primate ventral pathway are selective for faces (Tsao et al., 2006). At the same time, even putting aside the question of how this single-neuron selectivity translates into a visual understanding of objects, few researchers believe that single neurons code for individual objects. Rather, it is commonly held that large populations of neurons carry information objects or object classes in a distributed fashion. This is nicely demonstrated in a recent study that explored how long-term experience with objects affects the response properties of both excitatory and inhibitory neurons within the inferior temporal region of the ventral pathway. Critically, experience had opposite effects on the two types of neurons, with excitatory neurons showing an increase in their maximal responses to their preferred highly-familiar objects and inhibitory neurons showing a decrease both in their maximal response to highly-familiar objects and in their average rates of response (Woloszyn and Sheinberg, 2012). Taken together, these two effects indicate that information about familiar objects is carried by a population of both excitatory and inhibitory neurons, whereby a 'balance' is maintained between excitatory neurons narrowly encoding information about object familiarity and inhibitory neurons broadly encoding information about object novelty. A different sort of evidence for population codes – somewhat indirect – is provided by single-neuron studies that systematically explore which separable object features yield neural activity equivalent to the maximal response observed for the complete object. In many instances,

the maximal response is maintained when highly schematic features are presented, suggesting that individual neurons must work in concert (Tanaka, 1996).

To the extent that individual neurons carry information derived from (images of) objects, there remains the question of format (Marr and Nishihara, 1978). Information can be more or less invariant over changes in the appearance of the object in the image. Ideally, perception and recognition should remain robust when an object changes its configuration, or is moved, rotated, or illuminated differently. Many object-selective neurons exhibit some invariance: the level of response to a preferred object is not dramatically affected by changes in the size or the spatial position of the object for which a given neuron is selective (Desimone et al., 1984). On the other hand, these same neurons often show great sensitivity to changes in pose or illumination direction. For example, a large percentage of object-selective neurons are also 'view-tuned' in that they show the highest level of activity to familiar objects in specific viewpoints (Logothetis and Sheinberg, 1996). Face-selective neurons may respond most strongly when presented with a frontal view of a face, but show a progressively diminished response as the face rotates away from this viewpoint (Perrett et al., 1985). Similarly, in the visual cortex of monkeys taught to recognize novel objects, neurons that become selective for these objects are typically highly tuned to the particular viewpoints used during training (Logothetis and Pauls, 1995). These findings are consistent with much of the behavioral data on object recognition, where recognition performance is often strongly dependent on the familiarity of a given viewpoint (Tarr and Bülthoff, 1998). Thus, at the finest scale of analysis, single neurons participate in a code that is generally invariant over size and location, but are sensitive to viewpoint and other changes in the image.

Hierarchical Processing in the Visual Cortex

How can single neurons or populations of neurons code the complex patterns and feature conjunctions present in almost all objects? Many models of object recognition assume that the answer is that object- or feature-tuned neurons are the endpoints of a hierarchy of progressively more and more complex visual codes (*see* Visual Perception, Neural Basis of). Supporting this approach, neurons in the earliest visual areas (*see* Occipital Lobe (Visual Cortex): Functional Aspects) respond to very simple, more generic properties of objects, for instance, oriented edges or blobs of color. As one moves 'up' the visual pathway (*see* Visual Streams: Dorsal and Ventral) the coding becomes more specific, with neurons at higher levels generally showing selective responses to more complex properties of objects than the level(s) below them (Van Essen and Maunsell, 1983). The principle behind this hierarchy is straightforward: from one level to the next, neurons respond only if they receive input from multiple neurons, thereby creating selectivity that is necessarily a product of a given neuron's inputs. This many-to-one principle not only pools information in the straightforward sense, but because of the pattern of connectivity from one layer to the next, assembles new and more complex features as one moves up the hierarchy. Given the strong evidence for this sort of feed-forward processing in the visual system, many computational models, even those that are quite dissimilar in other respects, have adopted a hierarchical processing architecture to capture complex object features (Marr and Nishihara, 1978; Riesenhuber and Poggio, 1999). Although the hierarchical approach is appealing, some theorists have pointed out that assembling complex features in this fashion may lead to overly selective neurons. That is, given too precise information about an object image, a neuron or population of neurons might be incapable of generalizing to new viewing conditions, even with only slight changes in the image.

To address this need for invariance over changes in the image, some computational models have adopted a hierarchical architecture in which there is an alternation between conjunctions of features – the standard hierarchical model – and disjunctions of features (Riesenhuber and Poggio, 1999). For example, one layer might consist of neurons that respond only if they receive input from a *collection* of neurons coding for simpler features, while the next layer might consist of neurons that respond if they receive input from *any* of several neurons. This sort of hierarchical coding is exemplified by a single neuron that codes for a three-dimensional object regardless of its orientation, but only by virtue of the fact that this view-invariant neuron is driven by any one of several view-tuned neurons, each coding for a different view of the same object (Logothetis and Sheinberg, 1996).

The Building Blocks of Object Selectivity

The hierarchical organization of the visual cortex suggests that information about objects takes the form of a 'vocabulary' of features constructed from simpler features (Marr and Nishihara, 1978). This assumption implies that somewhere between orientation-selective neurons in early vision and object-selective neurons at the highest levels of the ventral visual pathway, are neurons encoding information about the critical features that distinguish one object from another. Under one view, such features should look something like object parts; intuitively the first level of decomposition when we perceive objects (Marr and Nishihara, 1978). There is, however, little evidence to indicate that neurons coding for parts, as we typically construe them, are the precursors to object-selective neurons. When the responses of neurons in intermediate and high-level visual areas are systematically decomposed, they show consistent responses to patterns that are more complex than edges, but less complex than objects. However, these 'features' often appear arbitrary, coding for odd, almost random shape properties. For example, one neuron might respond most strongly to a lollipop shape, while another neuron might respond to an eight-point star (Tanaka, 1996). While such features may appear to be random or, at best, schematic versions of certain objects, they are not arrayed haphazardly across the visual cortex. Rather, as with most visual areas, there is a columnar organization in which neurons within a column all code for the same feature and adjacent columns tend to code for similar features, albeit with columnar boundaries sometimes representing dramatic changes in feature selectivity (Tanaka, 1996).

In contrast, more recent work has investigated responses of IT neurons in a principled way by morphing three-dimensional novel stimuli to map the tuning of neurons (Yamane et al., 2008). These data suggest that shape-selective

neurons may be capturing three-dimensional aspects of objects through selectivity to curvature-based features, as well their configurations. More recently, a study following up on this result found evidence for neural selectivity to both medial axis shape and surface properties (Hung et al., 2012), suggesting that high-level selectivity to objects may be based on an object's skeletal shape and surface appearance. Interestingly, this account is consistent with earlier computational models of object representation in which an object's medial axis and surface features comprised the essential 'building blocks' for describing objects (Marr and Nishihara, 1978; Blum, 1967).

Figure 1 A representative map on an inflated cortical reconstruction showing BOLD activity in the lateral occipital complex (LOC) selective for objects over scrambled objects.

How Large Numbers of Neurons Code Information about Objects

While significant advances in our understanding of high-level vision have arisen from studying the responses of single neurons, most theorists hold that the process of object perception is not captured by either individual neurons or small numbers of neurons. Object perception and recognition almost surely rely on population codes comprised of ten thousands or more neurons, with still larger populations recruited for the performance of specific tasks. Ideally we would like to measure the responses of many neurons spread across visual cortex simultaneously. Unfortunately, it is impossible to make such measurements using present-day single-unit or multi-unit recording methods. As an alternative, to explore the responses of large populations of neurons during object perception, functional MRI (fMRI) – which indirectly measures the activity of large populations of neurons using a blood oxygen level-dependent (BOLD) signal – has become a popular neuroimaging technique applicable to human subjects. The entire human brain can be imaged simultaneously, collecting signals from 100 000 to 400 000 'voxels' (volume pixels), the resolution of each voxel being between 2 and 3 mm^3 – a volume that covers approximately 10^6 neurons.

Object Selectivity in Human Visual Cortex

To investigate whether there exist populations of object-selective neurons within the human ventral visual cortex researchers have compared the BOLD signal evoked when viewing common objects to the signal evoked when viewing scrambled versions of those same objects or texture patterns (Malach et al., 1995; Grill-Spector et al., 1998). A typical result is that a region of lateral occipital cortex located somewhat posterior and inferior to motion-selective area MT/V5 exhibits a greater response to intact objects as compared to scrambled objects. In contrast, lower-level visual areas such as V1 show no such difference. This object selective region, identified consistently in many other studies (e.g., Kourtzi and Kanwisher, 2000), has been referred to as the lateral occipital complex (LOC) (**Figure 1**). But what is the nature of information about objects encoded within the LOC and what role does such information serve in the context of the larger object processing hierarchy? Although single neurons are often sensitive to image variations such as viewpoint or lighting, behaviorally we are capable of recognizing an object across such variations. As the pooled response of 1 000 000 of neurons, it is possible that LOC functionally encodes information about objects in an invariant manner that reflects our phenomenological experience (although it is worth noting that even when our recognition seems effortless, we are often slower or less accurate across novel image variations; Tarr and Bülthoff, 1998). Using fMRI 'adaptation' techniques in which reduced responses over repeated trials denote sensitivity to the repeated stimulus property (or lack of sensitivity to a varying stimulus property), it has been found that regions of LOC are both size and position invariant (Grill-Spector et al., 1999). Similarly, LOC appears to be invariant with respect to whether an object is presented as a gray scale photograph or as a line drawing (Ishai et al., 2000; Kourtzi and Kanwisher, 2000). However, whether LOC is invariant over changes in viewpoint is less clear-cut, with the degree of adaptation being dependent on the magnitude of the pose change (Grill-Spector et al., 1999; James et al., 2002) – a result that is actually quite consistent with the single neuron data in which larger changes in viewpoint lead to larger decreases in a neuron's spike rate. Finally, adaptation has also revealed that LOC responds in an invariant manner to moving objects (Pyles and Grossman, 2009), and to changes in lower-level features such as contours (Kourtzi and Kanwisher, 2001). Overall, there is accumulating evidence that LOC encodes critical information that is integral to our perceptual experience of a stable world in which changes in our viewing position or in the configuration of the environment do not perturb our perception of objects.

Category Selectivity within the Ventral Visual Cortex

LOC appears to encode object information in domain-general manner – that is, without regard to the semantics associated with a given object (e.g., its category and its function). In contrast, one of the most consistent findings across neuroimaging studies of human ventral visual cortex has been that there exist localized regions that respond preferentially to specific object categories. The most studied of these category selective areas is a region of the mid-fusiform gyrus (mFus) that shows significantly higher responses when observers view faces as compared to when they view common, non-face objects (Kanwisher et al., 1997; Sergent and Signoret, 1992). Similar functionally-defined, category-selective cortical regions have been identified for letters, places/scenes, houses, human body parts, tools, and moving objects (Epstein and Kanwisher, 1998; Cohen et al., 2000; Downing et al., 2001; Grossman and Blake, 2002).

Thus ventral visual cortex seems to show an organization based for at least some object categories, on high-level visual semantics. Moreover, as with single-neuron studies, fMRI likewise reveals that some of these categories – notably faces and body parts – consistently evoke preferential responses in multiple brain areas and that these areas have consistent anatomical locations and spatial relationships with one another (Weiner and Grill-Spector, 2011; Pyles et al., 2013). Reiterating our earlier points, the existence of multiple category-selective brain regions for a single object category indicates that localized selectivity in and of itself does not denote phenomenological association with the perception of that category. Rather it seems likely that each localized brain region realizes a category-critical computation or computations within a larger functional network.

Large-Scale Coding of Objects

Beyond the idea that category-selective brain regions should be considered as participants in larger functional networks, the entire concept of category selectivity, as measured by fMRI, may be misleading. In particular, evidence for localized category-selective brain regions typically comes from comparing the responses associated with one object class to the responses associated with a second object class; for example, comparing face-related responses to house-related responses. Such comparisons, almost by definition, give rise to clustered, localized differences that mask the overall pattern of responses across much of the ventral visual pathway (Friston et al., 2006). In truth, *any* object category produces a complex pattern that is almost always different – on a voxel-by-voxel basis – from the response patterns arising for any other categories of objects (otherwise how else could we tell them apart?). Of course, although logically present, these differences are often subtle and relatively small compared to the large differences seen between highly-overlearned visual categories, such as faces, scenes, and words. Yet such subtle differences are likely to be critical elements in the neural code. Multivariate pattern analysis (MVPA) addresses this issue, considering the pattern of neural responses associated with an object or object category (Norman et al., 2006). Beyond enabling exploration of more subtle aspects of object coding, MVPA allows one to move beyond studying neural responses only in functionally localized or neuroanatomically-defined brain regions, instead using systematic 'searchlight' methods to interrogate the neural coding of information across the brain (Kriegeskorte et al., 2006). For example, one study using MVPA observed complex response patterns across large portions of ventral visual cortex that reflected different high-level properties of objects, such as animacy, natural kind status, and human/not human (Kriegeskorte et al., 2008). Still more ambitious studies have mapped out the neural encoding of high-level semantic space for a wide variety of object and action categories (Huth et al., 2012). Interestingly, in the former study, using the same object images in both human fMRI and primate neurophysiology, neurons in primate visual cortex showed a similar pattern of featural organization to that revealed using fMRI (Kriegeskorte et al., 2008). More generally, exploring the subtle response patterns of large-scale neural populations in an unrestricted manner across the entire brain has enabled the identification of functional regions involved in object perception that might have otherwise been overlooked. For example, a region of anterior temporal lobe was recently identified as playing an important role in the processing of identity in human faces using MVPA (Nestor et al., 2008, 2011). Overall, the application of modern machine learning and statistical methods – as exemplified in MVPA – promises to shed more light on the featural basis of object perception as realized both throughout the brain and, particularly, within the ventral visual cortex.

Organizing Principles of Object Selectivity

One question that is rarely asked with respect to the organization of ventral visual cortex is *why* it is organized as it is? That is, why do some object categories give rise to category-selective responses, while other categories appear to produce only more distributed patterns of responses? Moreover, in that humans, almost all exhibit a similar functional organization across ventral visual cortex, why do particular category-selective regions consistently localize to approximately the same neuroanatomical locations across individuals? There are at least two accounts for this common neural organization across individuals. Under one account, different category-selective brain regions are functionally fixed as domain specific. That is, regions are category-selective for faces, bodies, or scenes because this high-level selectivity is intrinsic to our neural architecture (Kanwisher, 2010). In contrast, an alternative account posits that a variety of low-level constraints shape which visual inputs are processed in different regions of the ventral visual cortex. That is, given the structure of the input, task demands, and connectivity constraints, particular visual object categories are processed and encoded in brain regions that are biased toward those image structures, tasks, and connectivity to support further processing.

For example, one recent fMRI study found that face-selective regions, including mFus, are recruited when observers view displays with predominantly curved contours, but that scene-selective brain regions are recruited when observers view displays with predominantly straight contours (Tootell et al., 2012). Thus, low-level image statistics, including curved versus straight, appear to play an important role in determining which high-level brain mechanisms ultimately end up processing different object categories, for instance, faces and scenes. With respect to task, a second recent fMRI study manipulated whether observers were trained to recognize novel objects at the individual or the basic (categorical) levels. Critically, individuation training produced an increase in object-selective neural responses within the mFus, while categorical training produced an increase in object-selective neural responses along the medial portion of the ventral occipito-temporal cortex (Wong et al., 2009). Thus, the particular task associated – by default – with a specific object category appears to also play some role in determining which high-level brain mechanisms end up processing those categories. Finally, there is evidence that the visual word form area – a brain region selective for written letter strings – and the face-selective mFus localize to the left and the right hemispheres, respectively, because of competition between the two domains (Behrmann and Plaut, 2013). In particular, connectivity to left-lateralized brain areas

specialized for language processing seems to dictate that brain regions supporting visual reading skill are also co-localized to the left hemisphere. Thus, the ways in which different high-level brain mechanisms are functionally connected to other neural systems helps to determine which visual object categories are likely to end up being processed by those mechanisms. In sum, the answer to the question of why particular category-selective regions are located where they are in the brain may have more to do with a host of relatively low-level biases within the architecture of the visual system rather than any pre-specified high-level constraints on which domains are processed where.

The Functional Role of Localized Brain Regions

Beyond asking why the ventral visual cortex is organized as it is, we must ultimately address the question *how* these many neural structures combine to produce complex visual behavior. As we have discussed, neuroimaging methods are useful for localizing *where* in the brain particular computations occur. Moreover, neuroimaging has increasingly focused on the functional nature of these computations – that is, the specific roles different neural substrates play in producing a behavior. This more recent trend builds on neuropsychological methods that have been historically used to explore deficits in behavior as a direct consequence of brain injuries to particular brain regions. For example, the existence of category-selective brain regions sensitive to faces was predicted by earlier neuropsychological research in which damage to regions such as mFus were observed to impair face recognition. Similarly, wider damage within the ventral visual cortex can result in the loss of one's ability to visually recognize many or all object classes – a syndrome known as *agnosia* (*see* Agnosia). Although these patients are grouped under this single label, agnosia includes damage to many different regions of the visual cortex and many different visual recognition deficits.

One of the ways in which neuropsychology has informed our understanding of the neural encoding of objects, has been through the deficits associated with damage to specific brain regions. As with the neuroimaging literature, the identification of category-specific visual recognition deficits has been taken as evidence for computationally 'modular' brain structures dedicated to singular visual domains. To take one example, if this modularity argument is correct for face processing, then damage to the brain region specialized for faces should result in deficits that are exclusive to face recognition and no deficits for non-face object recognition. Such a pattern would imply that the damaged region was functionally domain-specific (for faces). Thus, knowledge regarding the location of a brain injury, in tandem with a pattern of sparing and loss in behavior, may help reveal the functional roles of intact and damaged brain regions (*see* Cognitive Neuropsychology, Methods of). As mentioned, for face processing, patients with injuries to their ventral visual cortex often suffer a specific form of agnosia referred to as *prosopagnosia* (*see* Prosopagnosia) in which face recognition appears to be disproportionally impaired relative to object recognition (Farah, 1990). At first blush, the existence of prosopagnosia would seem to reinforce the idea of category-specific brain regions exclusively sensitive to faces. Indeed, it is known that damage to the right mFus in particular will typically give rise to impairment of visual face recognition. However, prosopagnosia can arise as a consequence of damage to brain regions other than mFus (Barton, 2008). Even more telling is the fact that developmental prosopagnosia – that is, prosopagnosia that does not occur as a result of brain damage – can also arise due to structural connectivity differences within the ventral visual cortex (Thomas et al., 2009). Indeed, individuals with developmental prosopagnosia typically show *normal* mFus responses as measured by fMRI, yet impaired ability to individuate faces. Thus, one must be cautious in attributing category-specific impairments to damage to putatively category-specific brain regions. Reinforcing the need for caution in interpreting neuropsychological patterns of sparing and loss, there are studies demonstrating that when prosopagnosic patients perform difficult individual-level discriminations with non-face objects (e.g., snowflakes), they show equal impairment with faces and non-faces (Gauthier et al., 1999). Thus, the nominally face-specific mechanisms damaged in cases of prosopagnosia are actually implicated in the processing of non-face objects, suggesting that, as with the category-selective responses seen in neuroimaging, category-specific deficits should be considered in a larger context of tasks and more complex brain networks.

Abstract

Binding operations, the dynamic establishment of semantic relations between distributed computational results, are key functions of cognitive processes in the brain. A common binding strategy is anatomical convergence of feature-encoding neurons onto conjunction-specific cells that respond only if the respective constellation of features is present. It is argued that this binding mechanism needs to be complemented by a more flexible mechanism that allows the brain to define relations on the fly in order to account for the nearly unbounded ability of evolved brains to represent the ever-changing constellations of elementary features characterizing perceptual objects. Evidence is reviewed which suggests that such dynamic encoding of relations is achieved by synchronization of temporally structured neuronal responses and hence by convergence in the time domain. A hallmark of neuronal responses is their oscillatory patterning that concentrates discharges to a particular phase of the oscillation cycle. By self-organized phase locking of these oscillatory responses the discharges of neurons can be synchronized. This in turn jointly enhances the saliency of the synchronized responses and establishes unequivocal relations among them. Neuronal oscillations cover a broad frequency range but here mainly the high-frequency oscillations in the beta- and gamma-frequency range are considered as these have been investigated most thoroughly in the context of binding functions.

The mammalian brain is a highly distributed system in which a large number of different processes are executed in parallel and there is no singular center for the joint evaluation of the numerous, simultaneously obtained computational results. This raises the question of how partial results of the distributed computations are bound together in order to support the generation of coherent percepts, the convergence of decision processes, the coordination of executive actions and last but not least the unity of conscious experience. Such binding problems present themselves at all levels of processing, both within and across modalities. The reason is that the brain's connectome (the comprehensive map of neural connections in the brain) has small world properties, allowing for very efficient communication between nodes irrespective of their anatomical distance. The prevailing objectives are reciprocity of connections both within and across processing streams (van den Heuvel and Sporns, 2011; Markov and Kennedy, 2013). In principle, there are two complementary strategies for the implementation of binding functions, i.e., for the encoding of relations between neuronal responses. The first relies on spatial convergence of afferents (neurons that carry signals from the sense organs to the central nervous system) onto common target cells. In this case relations between the responses of the feeding neurons are encoded by the conjunction-specific responses of the target cells. The second uses time as coding space for the expression of relations. In this case relations are expressed by temporal coordination of distributed responses. Thus, relations can be encoded by either conjunction in space or conjunction in time. The two mechanisms coexist and complement one another.

The binding of signals that occur very often in conjunction or whose contingent occurrence is of particular behavioral relevance is achieved mainly through conjunction-specific neurons that are formed by anatomical convergence in hierarchically organized architectures. The binding of infrequent or novel constellations of signals is preferentially achieved by the formation of temporally coherent assemblies of neurons whose configuration changes rapidly and in a context-dependent way due to dynamic modulation of the coupling between neurons. Perceptual objects are defined by a unique constellation of features whereby the diversity of possible constellations is virtually unlimited. This requires versatile binding operations that are difficult to realize with conjunction in space because of the combinatorial explosion of required connections between feeder cells and conjunction-specific neurons. Combinatorial problems of similar magnitude have to be solved for the programming of movements. Although the elementary components – the contraction of individual muscle fibers – are limited in number, the diversity of movements that can be generated by combining the elementary components is again virtually infinite. Evolved brains have acquired an extraordinary competence to solve such combinatorial problems and it appears that this is achieved by the combination of binding operations that exploit the options to encode relations both by conjunction in space and time.

Two Complementary Binding Strategies

In the primary visual cortex of mammals, relations among the responses of retinal ganglion cells are evaluated and represented by having the output of selected arrays of ganglion cells converge in diverse combinations onto individual cortical neurons. Distributed signals are bound together by conjunction-specific neurons that signal elementary feature constellations (Hubel and Wiesel, 1962). Through iteration of this strategy neurons in higher cortical areas acquire increasingly sophisticated response properties, representing complex constellations of features and, in special cases, even whole perceptual objects (Gross, 1992; Tanaka, 1997; Quian

 http://dx.doi.org/10.1016/B978-0-08-097086-8.55038-7

Quiroga et al., 2005). A similar organization is manifested in each of the other sensory modalities.

However, the strategy to represent relations explicitly by responses of specialized conjunction cells is constrained by the combinatorial explosion of the number of required binding units. This combinatorial problem is further accentuated by the fact that perceptual objects are often defined by conjunctions of features encoded in different sensory modalities. Most objects are characterized by a specific combination of visual, haptic (touch), or acoustic properties. Finally, difficulties arise if novel objects with unfamiliar feature constellations need to be represented because it appears only marginally feasible if not impossible to a priori generate a pool of conjunction-specific cells for the unfamiliar or to rearrange anatomical convergence on the fly in response to a novel object. These problems can be overcome by encoding relations through temporal conjunction because it permits utilization of the same neurons for the representation of different objects (Hebb, 1949). Here, the constellation of features characterizing perceptual objects is thought to be represented by the temporally coordinated activity of a dynamically associated ensemble of cells, whereby each of the participating neurons represents explicitly only subsets of features that characterize a particular perceptual object. Different objects can then be represented by recombining in various constellations neurons tuned to elementary features or their characteristic, frequently occurring combinations. The advantage of such distributed codes is that a particular cell can participate at different times in different assemblies. This sharing of neurons economized on neuron numbers and copes effectively with the huge combinatorial space occupied by real-world objects.

For assembly coding two constraints need to be met, however. First, a selection mechanism is required that permits dynamic, context-dependent association of neurons into distinct, functionally coherent assemblies. Second, grouped responses must get labeled so that they can be distinguished by subsequent processing stages as components of one coherent representation and do not get confounded with other unrelated responses.

Such labeling can be achieved by jointly raising the saliency of the selected neurons, because this ensures that they are processed and evaluated together at the subsequent processing stage. Neuronal systems have three options to increase the relative saliency of selected responses: First, non-grouped responses can be inhibited; second, the discharge frequency of the selected responses can be enhanced; and third, the selected cells can be made to discharge in precise temporal synchrony. Inhibition simply eliminates potentially confounding signals, enhanced firing raises the impact of the selected responses through temporal summation and synchronization raises the saliency of responses through spatial summation of synaptic potentials and exploits the exquisite sensitivity of neurons to coincident excitatory inputs (Singer, 1999). Modulation of discharge rates is a common and well-characterized signaling mechanism but it has certain disadvantages in the context of distributed coding. First, discharge rates of neurons depend on a large variety of variables and hence cannot signal unambiguously whether a cell has become part of an assembly. Increases in discharge rate resulting from changes in stimulus intensity and context would not be distinguishable from those signaling membership of a cell in an assembly. Ambiguities could also arise when different assemblies need to be configured simultaneously at the same processing stage. This may be the case when different objects and their relations to one another need to be represented simultaneously. If the corresponding assemblies were defined solely by enhanced discharge rate of their member neurons it would be difficult to distinguish which of the enhanced responses belongs to which assembly. These ambiguities can be reduced if the cells participating in an assembly synchronize their discharges with high temporal precision because synchrony can be adjusted independently of rate fluctuations (Lima et al., 2011). Moreover, relations between responses can then be defined with very high temporal resolution because synchronization enhances only the saliency of those discharges that are precisely synchronized and generate coincident synaptic potentials in target cells at the subsequent processing stage. In case of response selection by synchrony the selected events are individual spikes or brief bursts of spikes and not the overall increase in discharge rate. Thus, relations can be defined on short timescales. This permits temporal intercalation of different assemblies whereby the rate at which assemblies can be multiplexed without getting confounded is limited only by the duration of the interval over which synaptic potentials are integrated. This interval depends on the time constraints of neuronal membranes and for cortical neurons is in the range of 10–15 ms. These integration windows can be further shortened if neuronal networks engage in oscillations. In this case cells are exposed to periodic volleys of inhibition, which further shorten the window over which cells can effectively integrate excitatory inputs. With high oscillation frequencies (>40 Hz) these windows of susceptibility may be as short as a few milliseconds. Thus, different assemblies can coexist within the time span of perceptual presence without getting confounded.

Synchrony as a Signature of Relatedness

The discharge of neurons in the cerebral cortex reflects with great precision the temporal structure of stimuli. Synchronously presented stimuli evoke synchronous responses. This makes it possible to examine with psychophysical experiments whether synchrony of responses is indeed interpreted as a signature of relatedness. The results of biophysical studies indicate that the synchronous responses evoked by simultaneously presented stimuli are indeed bound perceptually and get segregated from the temporally offset responses evoked by asynchronously presented patterns of elements. In the visual system the temporal resolution for the perceptual binding of synchronous responses and the segregation of asynchronous responses is better than 10 ms (for review, see Singer, 1999). This suggests that precise temporal relations among the discharges of distributed neurons are exploited for perceptual grouping and segregation, respectively, and that offset intervals are used for segregation that are considerably shorter than those that allow one to determine the sequence order of rapidly presented stimuli.

In the mid-1980s, it was discovered that neurons distributed across the visual cortex can synchronize their discharges

with millisecond precision when activated by a single visual object (Gray and Singer, 1987, 1989). This synchronization is caused by dynamic interactions between cortical neurons that lead to phase locking of oscillations. Cortical networks get entrained in such oscillatory activity when in the appropriate state and activated by sensory stimuli: Typically, these stimulus-induced oscillations occur in the frequency range of 30–90 Hz, the so-called gamma-frequency band – and are due to local reciprocal interactions between excitatory and inhibitory neurons. Based on the theoretical considerations expounded above it had been proposed that this internal synchronization serves to establish relations between distributed responses by jointly raising their saliency and favoring their processing at subsequent processing stages. Since then numerous experiments have been performed in order to test predictions derived from this hypothesis (for review see Singer, 1999; Engel et al., 2001; Fries, 2009). This required demonstration that (1) synchronous activity is computationally relevant and has a stronger impact on target structures than nonsynchronous activity, (2) synchrony can be established and changed sufficiently rapidly to be compatible with processing speed, and (3) synchronization is involved in cognitive and executive processes requiring dynamic selection and binding of responses. Examples for such functions are feature binding and perceptual grouping, cross-modal integration, selection and binding of pattern elements by attention, temporary association of stored items in working memory, and the coordination of novel movements. All these functions have in common that relations have to be encoded on the fly and in ever-changing constellations between responses of widely distributed neurons on the backbone of the fixed network of anatomical connections – a function difficult to realize with conjunction-specific neurons that are specialized for the encoding of distinct relations.

Rapid Synchronization

Both simulation studies with spiking neurons and recordings from the brain revealed that networks could undergo very rapid transitions from uncorrelated to synchronized states (e.g., Gerstner, 1996; Vicente et al., 2008). One factor contributing to rapid synchronization is phase locking of oscillatory activity, which is an emergent property of networks consisting of reciprocally coupled neurons. Another mechanism enabling very fast and context-dependent synchronization of responses to sensory stimuli is based on correlated spontaneous oscillations. In the visual cortex neurons with related feature preferences are reciprocally coupled and this has the effect that they tend to oscillate synchronously even without stimulation (Fries et al., 2001a). These self-generated patterns of synchronized oscillations reflect the architecture and the weights of the intracortical association connections, which are held responsible for the grouping and binding of responses. Spontaneous activity can thus be considered as the reflection of a continuous readout of the grouping criteria that reside in the functional architecture of cortical connections. Because of these ordered patterns of self-generated oscillations grouping by synchronization can be extremely fast and occurs as a function of both the prewired associational dispositions and the current functional state of the cortical network. Upon arrival of retinal signals, cells already engaged in coherent oscillations instantaneously generate precisely synchronized discharges.

Relation to Perception

Stimulus-induced synchronization does not simply reflect anatomical connectivity but depends critically on the configuration of the stimuli. It is the result of a dynamic and context-dependent self-organization process that follows some of the Gestalt rules that govern perceptual grouping. In the visual domain this has been shown for the criteria of continuity, proximity, similarity in the orientation domain, colinearity, and common fate (Gray et al., 1989; Castelo-Branco et al., 2000; for review, see Singer, 1999; Uhlhaas et al., 2009).

Most of the early experiments on response synchronization were performed in anesthetized animals but more recent evidence indicates that internally generated synchrony is even more pronounced in the awake brain, exhibiting similar sensitivity to context (Kreiter and Singer, 1996; Buschman et al., 2012), and becoming particularly precise when the electroencephalogram (EEG) is desynchronized (Munk et al., 1996) and the animals are attentive (Roelfsema et al., 1997; Steinmetz et al., 2000; Fries et al., 2001b).

Direct relations between synchronization of oscillatory responses and cognitive functions have been found in strabismic amblyopia ('lazy eye') (Roelfsema et al., 1994), a developmental impairment of vision. Here synchronization of responses from the amblyopic eye is disturbed which accounts well for the reduced visual acuity, the perceptual distortions and the impaired figure-ground segregation in amblyopic vision, given that binding by synchrony serves perceptual grouping and disambiguation of contour ownership. Moreover, this finding agrees well with observations that entrainment of cortical networks in synchronous gamma oscillations reduces the variance of responses and increases signal-to-noise ratios (Rodriguez et al., 2004).

Another close correlation between response synchronization and perception has been found in primary visual cortex for the phenomenon of binocular rivalry (Fries et al., 1997). Responses from the eye that won in interocular competition increased their synchronicity while the reverse was true for responses from the eye that became suppressed. Interestingly, however, there were no rivalry-related changes in the discharge frequency of the neurons. This supports the notion that the saliency of responses can be enhanced either by increasing discharge rate or synchrony. The perceptual equivalence of the two saliency-enhancing mechanisms has recently been demonstrated (Biederlack et al., 2006). Evidence from noninvasive EEG and magneto-encephalographic (MEG) recordings in human subjects indicates further that access to consciousness is gated not only by enhanced sensory evidence and stimulus saliency but also – and to a crucial extent – by the synchronization of neuronal responses in extended cortical networks (Melloni et al., 2007; Gaillard et al., 2009).

The State Dependence of Response Synchronization

Converging evidence from human and animal studies indicates that synchronization of high-frequency oscillations in the beta- and gamma-frequency range is exquisitely state-dependent and increases with arousal, attention and expectancy to act. Preparation for the execution of sensory-motor tasks is associated with the formation of widely distributed cortical networks characterized by phase synchronization in the beta- and/or gamma-frequency range (Roelfsema et al., 1997; Womelsdorf et al., 2007). The expectancy of having to react to a visual stimulus leads to a massive enhancement of synchronized gamma oscillations in the primary visual cortex (Lima et al., 2011) and focusing attention is accomplished by the formation of synchronized networks comprising prefrontal and parietal cortical areas (Gregoriou et al., 2009, 2012; Buschman and Miller, 2007). In early visual areas responses to attended stimuli get entrained in gamma oscillations and phase lock with responses in subsequent areas of the processing hierarchy (Fries et al., 2001b; Bosman et al., 2012). It is assumed that this attention-dependent synchronization serves response selection by enhancing the saliency of selected responses and facilitates propagation of these responses across subsequent processing stages by phase locking of oscillatory activity (Fries, 2005).

Disturbed Synchronization in Psychiatric Diseases

Some of the cognitive deficits characteristic for mental diseases such as schizophrenia and autism spectrum disorder suggest abnormalities in binding functions and large-scale coordination of cortical networks. Motivated by the evidence that synchronization of oscillatory activity has numerous functions in sensory processing and also plays a major role in the formation of functional networks supporting working memory (Miltner et al., 1999) and that these functions are severely impaired in these diseases, patients were studied with EEG and MEG in search of abnormalities in oscillations and synchrony. The results obtained so far are unequivocal. Both diseases are associated with marked anomalies of these dynamic variables (for review see Uhlhaas and Singer, 2006, 2012). Patients show deficits in the ability to generate high-frequency oscillations and/or to synchronize oscillatory activity across cortical areas and these deficits correlate with the severity of the clinical symptoms. It is hoped that further study of the electrophysiological signatures will shed new light on the pathophysiology of these mental diseases and eventually lead to the identification of reliable endophenotypes.

Epilogue

The discovery of stimulus-induced response synchronization and the proposal that synchronization might serve as a neuronal code for the definition of relations have solicited highly controversial debates in the scientific community. Arguments raised in this context have been summarized in a series of reviews published in the journal *Neuron* (1999, vol. 24: pp. 7–125). These contributions focus on the putative role of synchronization in visual perception as the early studies have investigated mainly sensory processes. In the meantime oscillatory patterning and synchronization of responses have been identified as ubiquitous phenomena not only in and between areas of the cerebral cortex but also in the cerebellum and in subcortical structures such as the hippocampus and the basal ganglia. Oscillation frequencies vary across different structures and often one observes cross-frequency coupling; i.e., a fast oscillation is modulated in phase and/or amplitude by a slower oscillatory process (Canolty et al., 2010). It is suggested that such concatenation of rhythms serves the encoding of nested relations.

Taken together complementary evidence from animal studies and electrophysiological recordings from human subjects suggest that an oscillatory patterning of neuronal activity in the beta- and gamma-frequency band and the synchronization of this oscillatory activity serve a wide diversity of functions, such as feature binding and perceptual grouping, attention-dependent input selection, the dynamic formation of functional networks in the context of attentional control, working memory, and the coordination of movements (von der Malsburg et al., 2010; Uhlhaas et al., 2009).

At present, most of the evidence for the functional role of oscillations and synchrony is still correlative in nature as is the case also for the relations between other electrophysiological variables and behavior. The reason is the difficulty to selectively interfere with synchronization without affecting other response variables. It is undeniable, however, that the new approach – to register neuronal activity simultaneously from different sites and to search for temporal relations among the activity of distributed neuronal populations, rather than measuring only the rate variations of individual cells – provides new and fascinating insights into the dynamics of neuronal processes. In a number of investigated paradigms, changes in temporal correlations among distributed neuronal responses turned out to be a better predictor of stimulus configurations, of attentional states and of the outcome of a perceptual process than the rate changes of individual neurons. This suggests that the nervous system exploits the option to encode information in the precise temporal relations between the discharges of distributed neurons and the phase relations of oscillations. It is highly likely that massive parallel recording from large numbers of neurons will reveal that synchrony is merely a special state of the complex, nonlinear dynamics of the brain. It is one of the great challenges for systems neuroscience to decipher the alphabet of temporal codes in the high dimensional time series generated by dynamically interacting neuronal assemblies.

Abstract

Neuroeconomics is a recent, fast developing area of cognitive neuroscience, investigating the brain mechanisms involved in economic decision-making. It is an intrinsically interdisciplinary field, taking advantage of several mature areas of research including behavioral economics, neuroscience of reward, and reinforcement learning theories. This is a selective review of experimental evidence related to some key concepts of this vast domain, starting from early neuropsychological evidence of the role of the prefrontal cortex in decision-making and adaptive learning from experience. The role of the reward system, delineated by animal studies and explored in humans by means of functional neuroimaging methods as a key mechanism responsible for behavioral learning, has been extensively investigated in decision-making situations involving uncertainty, temporal delay, and the exploration of potential rewards. The theoretical framework of prospect theory has been used to investigate the neural mechanisms involved in anomalies of choice, in particular in loss aversion. Another important area of neuroeconomic research deals with the neural mechanisms involved in social contexts, i.e., those underpinning theory of mind and reciprocal trust. These multiple approaches are contributing to the rigorous study of individual differences in decision-making and of their neurobiological foundations.

Introduction

Economic decision-making, i.e., the identification of values and uncertainties involved in the production, distribution, and consumption of goods and services, is a central component of human life. The investigation of the brain mechanisms responsible for the set of cognitive processes involved in the selection of one course of action among the manifold available options informs the area of research called neuroeconomics. This field, as any other area of cognitive neuroscience, is intrinsically interdisciplinary and takes advantage of different methodologies and research traditions (among others, experimental and behavioral economics, cognitive and social psychology, computational modeling) (Levallois et al., 2012). These multiple approaches converge on the notion of *adaptive behavioral learning*, the core issue of economic behavior (Ullsperger et al., 2014).

Neuropsychological Insights

The history of neuroeconomics is relatively short, although its beginnings can be traced back to the classical neuropsychological case study of Phineas Gage, a survivor of extensive damage to the medial prefrontal cortex with extensive changes in personality, which resulted, among other consequences, in faulty decisions in everyday life (Macmillan, 2002). The implications of this case were developed in particular by Antonio Damasio and Antoine Bechara (Damasio, 1994), who studied individuals in whom similar lesions, involving in particular the ventromedial prefrontal cortex (vmPFC), were associated with impaired decision-making in the absence of other relevant cognitive disorders (Bechara et al., 1997). In what would become a very famous experiment, the subjects were asked to play a gambling task based on four decks of cards. Unbeknownst to the player, two 'disadvantageous' decks were associated with high winnings in the first trials but even higher losses in the long run, while the two other ('advantageous') decks resulted in higher winnings overall. While the control subjects began to prefer the latter decks even before becoming consciously aware of such difference (i.e., an implicit behavioral learning), the patient group continued to select the former, even after they explicitly understood the effective strategy. This observation was one of the foundations of the 'somatic marker hypothesis,' i.e., the proposal that choices are driven not only by rational and explicit computations, but also by unconscious biases, resulting from previous emotionally laden experiences. As discussed later, this observation connects this first neuropsychological foundation of neuroeconomics with the neurophysiological approach, concerned with the investigation of the neural mechanisms of behavioral learning in the mesocorticolimbic dopaminergic pathway (see Schultz, 2007, 2013). It is noteworthy, indeed, that such a differential learning in the two groups reflected in opposite affective reactions to risky choices and their anticipated outcomes. While the normal subjects developed a psychogalvanic response before drawing a card from 'disadvantageous' decks, the patients failed to display any change in skin conductance even after being consciously aware of their risky nature. These clinical observations opened the avenue for the investigation of the interacting roles of cognitive computations and emotional responses during decision-making in healthy individuals, particularly with neuroimaging techniques. Patient studies, however, continue to provide important insights into the necessary role of specific brain structures in decision-making, even beyond the strictly 'economic' domain. This is the case of the neural bases of moral, rather than purely economic, decision-making, which have been shown to involve overlapping regions (Shenhav and Greene, 2010). In other words, the computation of the expected 'moral value' of a decision (number of lives lost/saved) engages the same regions activated by monetary rewards, and vmPFC damage results in 'pure

utilitarian' choices in personal moral dilemmas characterized by a high emotional charge (i.e., inflicting serious harm to one person to save five) (Koenigs et al., 2007). That is, in choices characterized by a privileged consideration of the aggregate benefit, ignoring the aversive reactions displayed by control subjects when evaluating the negative consequences of one's own choice for another's welfare.

Expected Utility, Evaluation, and the Reward System

The classical approach of economic theory is normative, i.e., it is based on what can be considered as the behavior of a fully rational decisional agent. According to the expected utility theory (EUT; von Neumannn and Morgenstern, 1953), the ideal economic decision-maker, when confronted with a choice situation, computes the expected utility of each option by integrating the (positive or negative) subjective value of its possible outcomes, weighted by their probabilities. This computation is followed by a comparison among the valuation results, and by the selection of the option associated with the highest utility. Making decisions thus entails learning, estimating, predicting, and updating the *values* associated with available options. This notion underpins both the interdisciplinary nature of neuroeconomics, and its potential explanatory power well beyond the strictly economic field. Indeed, the strict relationship, both in behavioral and neurobiological terms, between the notion of value and that of *reward* allows the grounding of neuroeconomics in one of the most advanced areas of neuroscience, i.e., the neurobiology of learning and motivation (e.g., Doya, 2008). This is a crucial point that has been missed by some of the critics of the application of neuroscientific methods to the economic and social sciences (e.g., Legrenzi and Umiltà, 2011). Far from being speculative, and based on loose and neophrenological interpretations of the functional role of a given brain region, neuroeconomics builds on extremely solid anatomical and physiological foundations.

Indeed, the functional anatomy of the reward system is well known, largely on the basis of extensive evidence from animal studies (for a comprehensive review see Haber and Knutson, 2010). Pharmacological, physiological, and behavioral studies have clearly indicated that the mesocorticolimbic dopaminergic pathway (see **Figure 1**), originating in the midbrain ventral tegmental area (VTA) and projecting to the nucleus accumbens (NAcc), amygdala and medial prefrontal cortex, is the crucial component of the valuation system (Rolls, 2000; Schultz, 2007, 2013). Early imaging studies in humans, based on pharmacological stimulations by cocaine, highlighted an extensive network of areas, extending, beyond the NAcc, to the amygdala and prefrontal cortex, activated by the *experience* of motivationally relevant stimuli (Breiter et al., 1997). A comparable network was then shown to be engaged by a crucial reward for humans such as monetary gains (Thut et al., 1997). In particular the vmPFC, implicated by neuropsychological studies, has been shown to represent the subjective value of different goods (food, nonfood, monetary gambles), when a decision to purchase is made (Chib et al., 2009; Plassmann et al., 2007), or when a trade-off between crucial choice parameters such as quality versus quantity is computed (Padoa-Schioppa and Assad, 2006). The interplay of this region with other frontal

Figure 1 Brain reward circuits. The major dopaminergic projections to the forebrain that underlie brain reward are shown superimposed on a diagram of the human brain: projections from the ventral tegmental area to the nucleus accumbens (ventral striatum), and prefrontal cerebral cortex. Also shown are projections from the substantia nigra to the dorsal striatum (caudate and putamen and related structures) that play a role in habit formation and in well-rehearsed motor behavior, such as drug seeking and drug administration. Neural mechanisms of addiction: The role of reward-related learning and memory. Annual Review Neuroscience 29, 565–598.

areas, and particularly the dorsomedial–dorsolateral frontal networks involved in cognitive control (Koechlin et al., 2003), was demonstrated by the observation that self-control while making choices is mediated by modulation of this region by the dorsolateral prefrontal cortex (dlPFC) (Hare et al., 2009).

Via the experience (or 'nonexperience') of rewards and punishments, valuation plays a central role in their anticipation, and accordingly in *behavioral learning*. An epochal step in the understanding of the functional properties of the reward system has been the development of the notion of 'reward prediction error' (RPE), based on the crucial concept of temporal difference learning (see Sutton and Barto, 1998). This notion derives from the identification of the response properties of midbrain dopaminergic neurons by Wolfram Schultz. The firing properties of these neurons are compatible with a process of comparison between expectation and outcome, a process that is at the basis of reinforcement learning (Schultz et al., 1997). A positive RPE (an outcome larger than predicted) increases firing rate and elicits a phasic response. A negative RPE (an outcome smaller than predicted) decreases firing rate and elicits a tonic response. A perfect match of expected and actual rewards (null RPE) does not engage the midbrain dopaminergic system. Learning to predict rewards is a crucial requirement of effective decision-making, and there is ample evidence that the dopaminergic encoding of the difference between expected and actual rewards computed in the NAcc is a critical mechanism of human reward-based learning (Schultz, 2007, 2013). Another crucial step in the interdisciplinary integration among the subfields of neuroeconomics was the discovery that reinforcement learning, mediated by RPE, accounts for both Pavlovian (stimulus–stimulus) and instrumental (stimulus–action) learning (Barto, 1995). In the former case, the signals in the ventral striatum (VS) and in the orbitofrontal cortex,

assessed on the basis of the neural response during Pavlovian conditioning in humans, paralleled the results of single-cell recording in monkeys, reflecting the properties of the RPE signal (O'Doherty et al., 2003). Instrumental conditioning is based on the acquisition of the contingencies between the organism's actions and the resulting positive and negative outcomes. One component process, the 'critic,' computes the temporal difference error and updates predictions about future rewards via the same neural system activated by Pavlovian conditioning, centered on the VS. A second component, the 'actor,' updates action plans in order to maximize reward via approach versus avoidance behaviors, in the dorsal striatum. In human subjects, indeed, the left anterior caudate nucleus, a component of the dorsal striatum, shows stronger prediction error-related responses in instrumental, compared with Pavlovian, conditioning (O'Doherty et al., 2004). The phasic prediction error signal provided by the midbrain dopaminergic neurons is also involved in situations in which the predictions are based on statistical inferences or logical reasoning (model-based learning), rather than on immediate reward contingencies (model-free learning) (see Daw et al., 2011). While the role of the dopaminergic system in the acquisition of models is unknown, the response properties clearly highlight the modulation of response by model-based predictions (Schultz, 2013). There is evidence that, in humans, providing explicit knowledge about cue-reward probabilities, which results in improved performance, has an impact on dlPFC activation, correlated to a decrease in VS–vmPFC activity (Li et al., 2011). The computation of what has been called a 'state prediction error' in model-based learning (the state that is expected on the basis on the previous states and choices) has been shown to involve the lateral prefrontal cortex and the intraparietal sulcus (IPS) (Glascher et al., 2010).

Besides the amount of reward, another crucial determinant of expected utility is its *probability*. Probability results in *uncertainty*, which is maximal at $p = 0.5$, and zero at $p = 0$ and $p = 1$. Animal studies show that the midbrain dopamine system separately codes probability (by a monotonically increasing response, when the conditioned stimulus predicting reward is presented) and uncertainty (by a gradual increase in activity, peaking for $p = 0.5$, between the conditioned stimulus and potential time of reward) (Fiorillo et al., 2003). Neuroimaging studies in humans have highlighted, at the whole-brain level, the neural mechanisms of outcome anticipation in uncertain situations, showing that uncertainty is correlated with activity in the lateral orbitofrontal cortex (Tobler et al., 2007). A further distinction, which reflects in different patterns of brain activity, concerns *risk* and *ambiguity*, i.e., when probabilities are, respectively, known or unknown. Ambiguous, compared with risky, situations recruit inferior frontal and posterior parietal brain regions, both when ambiguous outcomes are passively perceived (Bach et al., 2009), and when a decision has to be made (Huettel et al., 2009). The latter study reported an interesting dissociation between these regions, highlighting the role of *individual differences* in risk preference on decision-making. Preference for ambiguity was predicted by activity on the lateral prefrontal cortex, and was inversely related to impulsivity. In contrast, risk preference was predicted by activity in the posterior parietal cortex. Neural signatures of risk-seeking versus risk aversion have been found during the anticipation phase of high-risk gambles (Rudorf et al., 2012). Risk adverse subjects, compared with risk-seeking ones, displayed a stronger response in the VS and anterior insula.

The timing of reward, and particularly the willingness to defer immediate gratification, is another important source of individual differences in decision-making, predicting academic achievement and other desirable outcomes (Duckworth and Seligman, 2005). A useful metrics of this behavioral trait is *delay discounting*, i.e., the decline of subjective value as a function of reward delay. Activity in the VS and vmPFC tracks delay discounting, as indicated by the decline in BOLD response paralleling the decrease in subjective value (Pine et al., 2010). Individual differences in the brain correlates of thinking about the future have been shown to predict delay discounting, suggesting that basic differences in temporal perception may be responsible for this crucial dimension of individual behavior (Cooper et al., 2013).

Behavioral learning, i.e., updating the value of stimuli and actions on them, requires also exploring the environment to gather information and thus decrease uncertainty. Exploring is intrinsically riskier than exploiting available knowledge, but the resulting novel information has a value of its own. The neural mechanisms subserving what has been called the *exploration–exploitation dilemma* have been studied using tasks in which the outcomes of the available options change over time, such as the classical 'four-armed bandit task.' This is a widely used decision-making task in which, on every trial, participants have to choose one among four slot-machines, whose payoffs differ and change slowly but continuously over time. By selecting a bandit and attending its current payoff, subjects can thus estimate and update its expected value at a given timepoint. The task highlights the value of exploring the decisional space because, although less risky in principle, choosing repeatedly the same bandit (i.e., exploiting) has a cost, i.e., the impossibility to learn the value of other options, as well as the possibility that previously collected knowledge is not up-to-date anymore. Optimal performance thus requires the ability to balance exploitative choices (i.e., choosing the bandit associated with the highest estimated expected value in a given timepoint) and explorative choices (i.e., choosing another bandit). At the neural level, the choice between exploiting current knowledge, and exploring in order to collect new one, involves a trade-off in the activity of two brain networks. While abundant evidence supports the role of the dopaminergic frontostriatal system in learning to exploit (Beeler et al., 2010), explorative decisions engage the IPS and frontopolar cortex (FPC) (Daw et al., 2006; Laureiro-Martinez et al., 2014a, 2014b; see **Figure 2** – top). Recent studies show that also the ability to timely switch between exploitation and exploration is subject to individual differences, involving the FPC. Activity in this region, particularly in the right hemisphere, tracks the value of alternative choices and predicts effective switching between exploitation and exploration (Boorman et al., 2009). Supporting evidence comes also from a recent study comparing brain activity of matched groups of entrepreneurs (i.e., people managing the organization they founded based on their venture idea) and managers (involved in making strategic decisions but with no

Figure 2 Top: The brain regions that were more strongly activated by exploitative than explorative choices (left), and by explorative than exploitative choices (right). Bottom: The relationship between behavioral decision-making efficiency (payoff divided by response time) at the 'four-armed bandit task' and estimated efficiency, based on the activity of regions which, in previous studies, showed a significant difference between exploitative and explorative choice (ventromedial prefrontal cortex, bilateral frontopolar cortex and intraparietal sulcus dorsal, sector of anterior cingulate cortex).

venture experience) engaged in the four-armed bandit task (Laureiro-Martinez et al., 2014a). Compared with managers, entrepreneurs showed higher decision-making efficiency (i.e., comparable payoff in shorter time), related to stronger activity in the same sector of the right FPC described by Boorman et al. (2009) (**Figure 2**-bottom), a finding that may be compatible with specific experience or with biological predispositions (see also Coates et al., 2009).

Prospect Theory and Anomalies of Choice

The advancements of neuroeconomics in mapping the critical nodes of the decisional brain, as well as the functional description of their role in terms of approach versus avoidance behaviors modulated by reinforcement learning, now provide a neurological interpretation to many of the human deviations from the normative rationality assumed by classical economic theories. Indeed, an important line of research at the crossroad between experimental economics, psychology, and decision science is based on a *descriptive*, rather than normative approach to decision-making, i.e., on the notion that many critical assumptions of EUT are systematically violated when real people make real choices (Tversky and Kahneman, 1974). Many resulting anomalies of choice have been investigated, including loss aversion (the higher sensitivity to losses than equivalent gains (Kahneman and Tversky, 1984)) and the framing effect (the different attitude toward risk when outcomes are framed as gains vs losses (Tversky and Kahneman, 1981)). A cognitive interpretation of both these anomalies is given by the doctrinal corpus of prospect theory (PT) (Kahneman and Tversky, 1979), which departs from EUT in several respects. First, in PT outcomes are separately coded, via specific value functions, as gains or losses with reference to a neutral reference point which is not the absolute zero. Second, the value function defined over losses is steeper than that defined over gains, which explains loss aversion. Third, both value functions display a logarithmic trend (concave for gains and convex for losses), which accounts for risk aversion in losses and risk-seeking in gains (i.e., the framing effect). While PT originally provided a cognitive interpretation of these anomalies of choice, i.e., in terms of cognitive functions translating normative values and probabilities in, respectively, subjective values and probability weights the increasing integration between such behavioral description and neuroscientific evidence extends this view, by highlighting individual differences in the balance among cognitive, emotional, and motivational factors involved in the processes of anticipation and valuation. Several studies, indeed, investigated the neural bases of human decision-making by focusing on the regions involved in the anticipation of prospective outcomes. The first study assessing brain responses to the expectation and experience of monetary gains and losses was reported by Breiter et al. (2001). This study firmly established the role of the mesolimbic 'reward' pathway, involving the NAcc, amygdala, and hippocampus, in tracking the monetary value of prospects. Subsequent studies related individual differences in the disposition toward specific anomalies of choices, such as framing effect and loss aversion, to the strength of activation in some of these brain structures.

Figure 3 The functional and structural neural basis of individual differences in loss aversion (see Canessa et al., 2013). Yellow to orange colors highlight the brain regions where brain activity is positively correlated with potential losses in decision-making under risk (bilateral posterior insula and middle cingulate cortex in the top part of the figure, right amygdala in its bottom part). Blue colors indicate a structural network including bilateral amygdala, thalamus, and striatum, in which source-based morphometry highlighted a positive correlation between loss aversion and gray matter volume. Red colors indicate the left amygdala cluster in which voxel-based morphometry highlighted a positive correlation between loss aversion and gray matter volume.

The neural bases of the framing effect were investigated by De Martino et al. (2006). Following seminal studies by Kahneman and Tversky, in every trial their subjects were asked to choose between a safe option ($p = 1$) and a gamble. In different trials, prospective outcomes were presented either as sure gains (e.g., keep 20 USD) or losses (lose 30 USD), or probabilistic gains (keep all with $p = 0.4$) or losses (lose all with $p = 0.6$), with respect to an initial endowment (e.g., 50 USD). The 'rational' expected values were thus identical across the four types of trials (i.e., safe-gain, safe-loss, gamble-gain, gamble-loss). According to EUT, rational decisions by a utility maximizer should thus be independent from the way prospects are presented. This, however, is not the case in the real world, and the framing of outcomes affected significantly the choice, with the 'loss' frame resulting in higher risk-taking than the 'keep' one. At the neural level, the activation of the amygdala was specifically associated with the framing effect, both when the sure option choice was chosen in the gain frame, and when the gamble was chosen in the loss frame. In contrast, when subjects were choosing against such general tendency increased activity was observed in the anterior cingulate and in the dlPFC. As it could be expected from previous behavioral evidence, the susceptibility of individual subjects to the framing effect was quite variable. This was reflected, in the imaging data, by a correlation between a 'rationality' index and activity in vmPFC, likely inhibiting aversive signals generated by the amygdala (Gottfried and Dolan, 2004).

The latter structure is also critical in generating individual differences in loss aversion when anticipating prospective outcomes, as shown by both lesion evidence in brain-damaged patients (De Martino et al., 2010) and neuroimaging data from healthy individuals (Canessa et al., 2013). Different neural mechanisms, however, appear to underlie the disproportionate weighting to losses than gains. One such mechanism specifically involves the VS, which displays a bidirectional response of activation for gains and deactivation for losses, with the steeper degree of deactivation versus activation reflecting individual differences in loss aversion (Tom et al., 2007). A recent study by Canessa et al. (2013) shows that loss aversion additionally reflects the activity of another mechanism, specific to the anticipation of losses and centered on the amygdala. In the latter study, subjects were asked to accept or reject mixed gambles offering equal (50%) chances of gaining or losing different amounts of money. The results highlighted both bidirectional and gain/loss specific responses while evaluating risky gambles, with amygdala and posterior insula specifically tracking the magnitude of potential losses. At the individual level, loss aversion was reflected both in limbic *f*MRI responses and in gray matter volume in a structural amygdala–thalamus–striatum network, in which the volume of the 'output' centromedial amygdala nuclei mediating avoidance behavior was negatively correlated with monetary performance (see **Figure 3**).

Outcome anticipation and ensuing loss aversion thus appear to involve multiple neural systems, showing functional and structural individual variability directly related to the actual financial outcomes of choices.

Social Decision-Making: Economic Exchanges, Cooperation, and Social Learning

Individual profiles of loss aversion, susceptibility to the framing effect, and intertemporal preference can be thought to summarize the essential features of a decision-maker, and to be able to predict her/his choice behavior. This model has been defined as a 'two dimensional' perspective (Rustichini, 2009). Economic decision-making, however, typically takes place in the context of social interaction, rather than in the isolated condition of the lottery gamble. The social nature of the human species thus reflects in the 'strategic' nature of many human choices, i.e., in decisional processes which need to take into account others', besides one's own, utility when evaluating prospective outcomes. While emotions and motivations play a key role in individual decision-making, the social context has been shown to enhance the weight of affective drives (Bault et al., 2008, 2011), as well as to recruit processes of social cognition associated with the understanding of others' intentions and emotions. This is the case, for instance, of 'trust' and 'cooperation' games which, not surprisingly, involve the ability to infer each other's mental states, i.e., Theory of mind or mentalizing (Premack and Woodruff, 1978). The study by McCabe et al. (2001) provided the first insights into the neural mechanisms involved in interpersonal exchange in a trust game. In this

study, subject A has to decide whether to select move x, which ends the game, or move b, which gives to subject B the possibility to move. In the former case, both subjects receive the same sum (e.g., 45). In the latter, the final outcome depends on B, who again has two choices: one gives to both increased winnings (e.g., 180 to A and 225 to B), while with the second she/he wins a large sum (e.g., 405) and the first subject gets nothing. Of course the choice of A depends crucially on her/his trust that B will reciprocate, while the choice of B depends on her/his perception of commitment toward reciprocation. The different payoffs were variable, in order to increase or decrease the incentive for cooperation. Crucially, subject B could be a human counterpart, or a computer deciding on the basis of fixed probabilities that were communicated to subject A. The main result is that most subjects decided to cooperate, and their prefrontal cortex was more active when playing with human subjects than with a computer. This difference was not seen in the minority of subjects who did not reciprocate.

Besides understanding another's intentions, sharing her/his emotional states has also an impact on decision-making. For example, different studies highlighted behavioral adaptations (i.e., increased vs decreased risk-taking) induced by both experienced and attended regret. These studies were based on a gambling task composed of several consecutive trials, requiring participants to choose between two gambles (Mellers et al., 1999). Gambles are depicted as 'wheels-of-fortune' in which different probabilities of variable amounts of gain or loss are represented by the relative size of colored sectors of the wheel. Immediately after the choice, the gambles are played and the results are shown. In different trials, participants are shown only the results of the chosen gamble (and thus experience satisfaction for a gain or disappointment for a loss) or the results of both the chosen and unchosen gambles (and thus experience relief or regret for a foregone outcome that might have been worse or better, respectively). Both lesional (Camille et al., 2004) and neuroimaging (Coricelli et al., 2005, 2007) evidence shows that the experience of regret, and the resulting behavioral adaptations, involve the vmPFC alongside the anterior cingulate cortex and the hippocampus. Canessa et al. (2009) used the same gambling task to test whether a 'resonant' neural mechanism is activated both when personally experiencing and when attending in someone else a complex emotion such as regret or relief. The participants either chose one of the two gambles, resulting in real gains or losses, or observed the same sequence of events (gamble evaluation, decision, and outcome evaluation) experienced by another individual playing the same task in a nearby room. The baseline was a condition in which the computer randomly chose one of the gambles, either for the participant or for the other player. Observing the regretful outcomes of someone else's choices activates the same regions that are activated during a first-person experience of regret, i.e., vmPFC, anterior cingulate cortex, and hippocampus (Coricelli et al., 2005). This finding suggests that the understanding of others' regret is mediated by the reactivation of the same brain regions that induce the feeling of regret in the beholder during a first-person experience. In a subsequent study, the same authors investigated whether this mechanism is also involved in learning from others' previous outcomes (Canessa et al., 2011). At the behavioral level the subjects changed their risk-aptitude in line with the outcomes of regret/relief of their previous decision, showing increased risk-seeking after 'relief for a risky choice' and 'regret for a nonrisky choice,' and reduced risk-seeking after 'relief for a nonrisky choice' and 'regret for a risky choice.' The same behavioral adaptation to previous experience was observed also after the *other player's* previous outcomes, while no significant change was observed after an outcome resulting from a random-choice by the computer. The latter finding indicates that the behavioral influence induced by one's own and others' previous outcome result from an emotional response associated with a *sense of responsibility*. This behavioral learning was reflected in cerebral regions specifically coding the effect of previously experienced regret/relief when making a new choice. Activity in subgenual cortex and caudate nucleus tracked the outcomes that increased risk-seeking (relief for a risky choice, and regret for a nonrisky choice). These regions were also more strongly activated by final risky, compared with nonrisky, decisions, and their conjoint activity is likely to reflect the motivational drive arising from previous outcomes that highlighted the reward-value of risky options. In contrast, activity in the vmPFC, amygdala, and periaqueductal gray matter reflected the outcomes reducing risk-seeking (relief for a nonrisky choice, and regret for a risky choice). All these regions, along with the anterior insula, were also more strongly activated while making nonrisky versus risky choices. The vmPFC likely reflects adaptive learning from past emotional experiences reducing risk-seeking and, via connections with amygdala, insula, and periaqueductal gray matter (Reynolds and Zahm, 2005) activates the negative feeling associated with regret and its anticipation. A subset of these regions reflected both first and third person previous outcomes when making new choices. This finding, that fits with the influence from others' outcomes highlighted by behavioral data, extends the concept of emotional resonance to the decisional domain, where such a shared response might act as one of the neural mechanisms underlying social learning. This mechanism would entail the mapping of the emotional consequences of others' choices on the same emotional states that are experienced as a first person, through the reactivation of the same cerebral regions that are involved in their direct experience.

The role of complex emotions in economic decision-making is also supported by studies based on the Ultimatum Game (UG) (Sanfey et al., 2003). This task involves two players that have to split a sum of money. The proposer decides how to split the sum, while the respondent can either accept the split or reject it. In the latter case, neither player receives anything. The theoretical implications of the UG are straightforward. The EUT prediction is that the respondent should accept any split, as any monetary outcome is better than nothing, and proposers should thus offer the smallest possible sum. Humans, however, do not behave this way, in that most proponents reject unfair divisions (see Camerer, 2003). The discussion about the possible reasons for this 'breach of rationality' by normal subjects is extensive, and open to different interpretations (Civai et al., 2013). The corresponding neural signature, however, is consistent, and involves emotional brain areas, in particular the anterior

insula, associated to negative emotional reactions such as those involved in pain and disgust (Wicker et al., 2004). Interesting converging evidence for a crucial role of this region in economic social exchange is provided by a study of borderline personality disorder (BPD), a clinical condition characterized by disruptive behavioral features which can be at least in part ascribed to defective cooperation. During a cooperative game based on multiple rounds of investment by healthy 'trustor' subjects, healthy trustees continued to cooperate, while BPD trustees failed to repay after the early rounds (King-Casas et al., 2008). This behavior was associated with a different activation profile in the anterior insula region. In healthy subjects, insular activity increased both with the sum received and the sum paid back, while only the latter response was observed in BPD.

Conclusions

From the economist's vantage point, the crucial question is whether the large and increasing neuroscientific evidence, of which we have given some selected examples, can be expected to have any impact on economic theories (Farb, 2013). As neuroscientists we cannot enter into this lively debate, but we can summarize what we consider as the most important implications of neuroeconomics for cognitive neuroscience. In the first place, the application of the rigorous and computationally explicit models of experimental economics to neuroimaging studies of human subjects provides a powerful tool for the investigation of individual differences in decision-making. The possibility to quantify variability in parameters such as risk aversion, loss aversion, delay discounting, explorative behavior, or cooperation is an important contribution of neuroeconomics research to the understanding of the neural bases of human behavior. In turn, evidence at the neurological level raises further questions whose implications exceed the domain of cognitive neuroscience. For instance, are these differences in behavior and neural activation the consequence of natural predispositions, or rather of brain plasticity phenomena consequent to training and experience? The former view is supported by studies of genetic polymorphisms, which, once again, typically highlight the role of genes affecting neurotransmission in regions associated with reward processing (e.g., dopamine modulation (Krugel et al., 2009)), amygdala reactivity (e.g., serotonin transporter 5-HTTLPR; (Crisan et al., 2009; Roiser et al., 2009)) and executive functioning (e.g., COMT gene; Frank et al., 2009; Golimbet et al., 2007). Studies of training effects are however needed to assess the possible role of neuroplasticity in the causation of individual and group-level differences, a topic of great interest also in terms of possible practical applications. A second, exciting area of application is translational neuroeconomics, i.e., the use of models and results of neuroeconomic research to increase our understanding of human disease. Many psychiatric and neurological disorders involve reward processing and decision-making, from addiction to personality disorders (Sharp et al., 2012), from Parkinson's disease (Schott et al., 2007) to frontotemporal dementia (Chiong et al., 2013). The possible impact of neuropharmacological manipulation has been already demonstrated for the dopamine system (Chowdhury et al., 2013), as well as for sexual hormones (Bos et al., 2010) and oxytocin (Declerck et al., 2010), while alternative ways to modulate the 'decisional brain' are already represented by neurostimulation techniques such as transcranial magnetic stimulation and transcranial direct current stimulation (Miniussi and Ruzzoli, 2013). As in most lively scientific fields, each empirical answer raises novel research questions, and this is one of the reasons why the interdisciplinary effort underlying neuroeconomics is one of the most exciting scientific challenges in contemporary cognitive neurosciences.

Abstract

Neuroendocrinology refers to the interaction of hormones related to brain functions, but also to the release and inhibition of other hormones affecting somatic functions. Basic principles of structure, transport, metabolism, and functions are elucidated, as well as the multiple interactions between hormones synthesized within the nervous system and those produced in peripheral glands and tissue cells of the organism. It is demonstrated that most hormones produced in the periphery also have receptors and functions in the brain. Furthermore, feedback loops, structural and functional relationships between hormone systems are described, as well as the role of hormones as indicators of transmitter functions.

Introduction

Neuroendocrinology refers to the interaction between the nervous and the endocrine system and can therefore be viewed as representing a link between endocrinology, concerned with effects of hormones released from endocrine glands on somatic functions of organs and diseases, and psychoneuroendocrinology, relating the mutual influences between the nervous system and hormones to psychological processes and dispositions. Therefore, some 'somatic' as well as 'psychological' aspects of the neuroendocrine system will be mentioned.

Definitions

The nervous (neurological) system is composed of the brain, spinal cord, and peripheral nervous system divided into the sympathetic and parasympathetic parts. The endocrine system refers to hormones secreted from glands as well as from neurons in the brain and peripheral nerves, and also includes hormones produced in tissue cells distributed in different organs. Hormones may act directly on specific target cells, may serve as releasers and inhibitors of other hormones, or may act as transmitters of electrical impulses in neurons or as cotransmitters (neuromodulators). Hormones, like the nervous system, serve the function of information processing in the organism and have in common that they are synthesized, secreted, and the ones produced remote from their target cells have to be transported by the bloodstream or by neurons. This gave rise to their name hormones (Greek hormao = I move). For exerting their action, most hormones have to bind to specific protein structures of the target cells called receptors.

History

Modern Neuroendocrinology may be viewed as a renaissance of the ancient Greek theory of the physician Hippocrates that body fluids are responsible for diseases as well as for temperament (blood = sanguinics, black bile = melancholics, yellow bile = cholerics and mucous = phlegmatics).

This was revived in the nineteenth century when interest arose in 'internal secretion' represented by the works of Claude Bernard, Thomas Addison, and Charles-Edouard Brown-Séquard, when the role of the thyroid in 1836, the adrenals in 1840, and the parathyroid organs in 1890 were first described (Cowadias, 1941). The role of certain substances isolated from blood and urine as indicators of functions of endocrine glands became evident when animal research revealed that extirpation of glands like the ovaries, the pancreas, or the thyroid led to certain deficiencies and diseases. Therefore, with growing interest in diseases related to internal glands, the relevance of these substances for therapeutic efforts increased. It was first pointed out by Brown-Sequard in 1889, although in the beginning only extracts from total glands could be used for therapy. The term 'hormone' was only created in 1905 by Ernest Henry Starling. In the first half of the twentieth century, most of the important hormones like glucocorticoids, gonadal hormones, growth hormone, and thyroid hormones had been identified. The interaction between hormones, their role in metabolism and, in particular, their control by the nervous system, and relations to psychological processes were only discovered and analyzed in detail during the first half of the twentieth century. With the analysis of their chemical structures, it became possible to use synthetic hormones and their derivatives for therapy most of which only became available after World War II.

Classification and Biochemical Properties of Hormones

Hormones may be classified according to their *structure* (polypeptides, glycoproteins, amino acid derivatives, and steroid hormones), their *site of synthesis* (neurohormones = produced in neural tissue, glandular hormones = produced in endocrine glands, and hormones produced in their target tissues (paracrine secretion)), and according to their *function*. The latter refers to growth, maturation reproduction, metabolism, circulation, regulation of temperature, balance of water and electrolytes, as well as to feeding, sleep, pain, affective states, and personality traits. There is large overlap between functions of different hormones and most of them are responsible for several different functions. They are often divided into endocrinologically acting hormones and cotransmitters, which are

Table 1 Glandular hormones according to sites of production and chemical classes

Organ or tissue	*Hormone or neuropeptide released*	*Chemical class*
Pituitary: anterior (glandular) part posterior part (=neuropituitary)	LH; FSH, ACTH, TSH, STH, PRL ADH (=AVP) OXT (=oxytocin)	Peptides, composed of amino acids
Parathyroid gland	Parathyroid hormone (parathyrin)	
Pancreas, Langerhans islets	Insulin, glucagon, somatostatin	
Pineal gland	Melatonin	
Thyroid	Thyroxin (T4); triiodothyronin (T3)	Tyrosine derivatives
Adrenal medulla	Adrenalin, noradrenaline, dopamin	
Adrenal cortex	Glucocorticosteroids, mineralocorticosteroids, androsteroids	Steroids, derived from cholesterol
Ovary	Estrogens, gestagens	
Testes	Androgens	

LH = luteinizing hormone, FSH = follicle stimulating hormone, ACTH = adrenocorticotropic hormone TSH = thyroid stimulating hormone, STH = somatotropic (=growth) hormone, PRL = prolactin, ADH = antidiuretic hormone = AVP = arginin vasopressin, OXT = oxytocin.

released in combination with transmitters and exert local paracrine functions by supporting the action of transmitters. Table 1 provides an overview according to their site of biosynthesis and class of chemical structure (for details, *see* Hypothalamus; Hypothalamic-Pituitary-Adrenal Axis, Psychobiology of)

The hormones are listed according to the three major classes of chemical structures: peptides (which include polypeptides and the glycoprotein hormones FSH, LH, and TSH = peptides carrying a carbohydrate side chain), tyrosine-based hormones (comprising catecholamines and thyroid hormones), and steroids (glucocortico- and mineralocortico-steroids and gonadal steroids produced in the adrenal cortex) and gonads.

The major biochemical and physiological differences between these classes of hormones are listed in Table 2.

It becomes evident that, although peptides and catecholamines belong to different classes of structures, they may follow similar principles. They are both released by exocytosis (ejection of the substance from vesicles in the cell) as opposed to the thyroid hormones and steroids, which leave the site of synthesis by diffusion. Similarly, the groups differ in their transport in fluids, which occurs as the free hormone or bound to a transport protein. Type of transportation may vary within the same hormone, depending on the type of fluid (steroids are bound to transport proteins in plasma, but are found in their unbound state in saliva, which is the effective form). The first two groups also differ from the third and fourth classes with respect to their ability to pass the blood–brain barrier, a structure that enables lipophilic substances like the thyroid hormones and steroids to enter the brain, while the hydrophilic classes of peptides and catecholamines are blocked. Similarly, differences in location of respective receptors and receptor

Table 2 Biochemical properties of the major classes of hormones

Property	*Peptides*	*Catecholamines*	*Thyroid hormones*	*Steroids*
Type of secretion	Exocytosis		Diffusion	
Transport	Free compound		Bound to plasma proteins	
Passage through blood–brain barrier	No		Yes	
Receptors				
Localization	Cell membrane		Nucleus	
Mode of action	Activation of second messengers		Control of transcription and mRNA	
Half life	Minutes–hours	Seconds	Days	Hours
Duration of action	Minutes–hours	Seconds–minutes	Days	Hours–days
Metabolic degradation	Proteolysis in plasma	By enzymes COMT, MAO	Glucoronidation and sulfatation in the liver	

mRNA = messenger ribonucleic acid, COMT = catechol-*o*-methyltransferase, MAO = monoamine oxidase.
Modified from Voigt, K.H., 2001. Endokrines system. In: Klinke, R., Silbernagel, S. (Eds.), Lehrbuch der Physiologie, third ed. Thieme, Stuttgart, p. 449.

functions are identical for peptides and catecholamines, on the one hand, and thyroid hormones and steroids, on the other. Yet, all classes differ in half-life (time until the concentration of the active compound measured in plasma has been reduced to half of its initial value). So catecholamines can only be measured for seconds after their release, followed by peptides, while steroids and thyroid hormones can be assessed hours or even days after release. These are important limitations in psychophysiological research, when activity of hormones is investigated by stimulating their release by stressors or drugs. There are also differences in catabolism: Cleavage of peptides to single amino acids is achieved by proteolysis, the catecholamines are metabolized by the monoamine-oxidizing enzymes MAO A and MAO B in brain and sympathetic nerves, and the thyroid hormones and steroids are metabolized by liver enzymes.

Functions of Glandular Hormones

The Pituitary

Most hormones have many different functions and most functions are mediated by the interplay and cooperation of several hormones. So hormones of an identical class, according to Table 1, may serve very different functions: Within the peptides released from the anterior lobe of the pituitary, the four glandotropic hormones *ACTH, FSH, LH, and TSH* stimulate the release of hormones in the adrenal cortex, the gonadal, and the thyroid gland (see Figure 1). ACTH is also important, because fractions of its amino acids (e.g., ACTH 4–9) have been shown to enhance memory (de Wied et al., 1993). *PRL* stimulates growth of the mammalian gland and, after rising at the end of pregnancy stimulates lactation after delivery, but it is also produced in males, responds to stressors, and is inhibited by dopamine. The most diversified functions are observed for

Figure 1 Regulation of hormones by limbic–hypothalamo–pituitary processes (↓ = stimulation; ⊥ = inhibition). *Transmitter level*: NE = norepinephrine, 5-HT = serotonin, DA = dopamine, Ach= acetylcholin. *Hypothalamic level*: CRF = corticotropin releasing factor, AVP = arginine vasopressin, ADH = antidiuretic hormone, GnRF = gonadotropin releasing factor, TRF = thyreotropin releasing factor, PRF = prolactin releasing factor, GHRF = growth hormone releasing factor. *Pituitary level:* ACTH = adrenocorticotropic hormone, FSH = follicle stimulation hormone, LH = luteinizing hormone, TSH = thyroid stimulating hormone, PRL = prolactin, STH = Somatotropic hormone, GH = growth hormone. Modified from Netter, P., 2005. Endokrines System und Persönlichkeit. In: Hennig, J., Netter, P. (Eds), Biopsychologische Grundlagen der Persönlichkeit. Spektrum Akademischer Verlag/Elsevier, p. 293.

the growth hormone *STH* (*GH*). It is responsible for growth of the bones during puberty and hence for protein synthesis, which needs support from the insulin-like growth factor IGF1 produced in the liver. STH also promotes lipolysis (breakdown of lipids) and may stimulate insulin production in pancreatic B-cell in a first step, but in a second step may inhibit transport of glucose into cells (antagonism to insulin).

The peptides *adiuretin* (*vasopressin* (*AVP*)) and *oxytocin* (*OXT*) produced in the posterior lobe of the pituitary (the neuropituitary consisting of neural tissue) and directly released into the bloodstream, again have different functions: AVP is responsible for water retention in the kidney and in higher concentrations for vasoconstriction, while oxytocin stimulates uterus contractions during delivery and participates in stimulation of lactation. Because of their particular relevance to behavior, these two peptides deserve a more thorough presentation. These two peptides are synthesized in the hypothalamus and transported to the neuropituitary by axonal transport from, where they are released into circulation. *Adiuretin* and oxytocin consist of nine amino acids each, differing only in two amino acids. Yet, there are several differences in functions: AVP, besides affecting reabsorption of water via V2 receptors at the site of the kidneys and exerting vasoconstrictive actions via V1 receptors at the arterial vessels, it also reaches the hypothalamus via the eminentia mediana, a paraventricular organ, where it supports CRF in stimulating ACTH as a hypothalamic releasing hormone of the HPA axis (see **Figure 1**), and thereby influencing its various psychological functions in relation to stress and emotions. In addition, AVP, like some other peptides, has been shown to enhance memory by acting on the ventral hippocampus, a process, which, however, is highly dependent on the time of application (at the beginning or at the end of the learning process) (Alescio-Lautier et al., 2000). AVP shares this observation with oxytocin and a number of other peptides and also with the ACTH fraction of amino acids ACTH 4–9 (de Wied et al., 1993). In addition, vasopressin has been investigated together with *oxytocin* with respect to social behavior. Oxytocin, known to be responsible for uterus contractions during labor and for ejection of milk from the mammarian gland, has been shown to be responsible for social bonding in animals (Insel et al., 1998) and humans (Uvnes-Moberg,1996; Heinrichs et al., 2009; Ebstein et al., 2012). This concerns mother–child interaction, sexual partnership as well as interpersonal trust in experimentally induced social interactions and social perception. It has always been discussed, if the two hormones, due to their structural similarity, act in the same direction or display opposite effects, oxytocin eliciting interpersonal trust, reducing anxiety, counteracting stress induced cortisol increases, perceiving threatening social stimuli as less aversive, and adiuretin being associated with anxiogenic interpretation of stimuli and aggressive feelings and behavior. Any reported differences may depend on the dimorphic actions of the two hormones, because some experimental findings obtained in males do not apply to females and vice versa. Nowadays, findings have partly been validated by neuroimaging studies (demonstrating e.g., that behavioral responses to the peptides are associated with changes in the activity of the amygdala) as well as by molecular genetics relating behavioral findings to polymorphisms of the OXT and the AVP receptors (Meyer-Lindenberg et al., 2011)

The Pineal Gland

Melatonin does not actually belong to the peptides because it is derived from serotonin, a transmitter based on the amino acid tryptophan and, unlike peptides, is lipophilic. Furthermore, the pineal gland, like the neuropituitary part, belongs to neuronal tissue. It is part of the circumventricular organs of the brain (see Section The Adrenal Cortex). Melatonin is inhibited by light and secreted at night. It regulates the day–night rhythm acting on the M1 and M2 receptors at the suprachiasmatic nucleus in

the hypothalamus (*see* Hypothalamus). Therefore, it has been used as a drug for compensating jet lag or disturbances of other rhythms underlying psychiatric diseases like depression. In addition, multiple actions of melatonin on many other tissues and systems like the immune system have contributed to its unjustified labeling as an antiaging substance.

The Parathyroid Gland

The peptide of the parathyroid gland, *parathyrin*, is responsible for the calcium–phosphate homeostasis regulating the stability of bones in cooperation with the tissue hormones calcitonin and calcitrole derived from vitamin D, but, as opposed to insulin, is not relevant for brain activities.

The Pancreas

The pancreatic cells type B of the Langerhans islets produce *insulin*, predominantly released upon consumption of carbohydrates and high levels of blood glucose. This is responsible for transport of glucose from the blood into somatic cells thus decreasing blood glucose, but it also has anabolic effects on fat and protein metabolism. In addition, insulin has receptors in the hypothalamus, where in combination with the tissue hormone leptin it may reduce food intake (satiety) and induce energy metabolism when both insulin and leptin reach high brain levels, while the reverse is observed for low brain levels (→hunger and increased food intake). Pancreatic A cells produce *glucagon*, an antagonist of insulin, which is released when protein rich food is consumed and blood glucose levels are low. It catabolizes glycogen stored in liver and muscles thereby increasing blood glucose. It can be modified by activation of catecholamine receptors forming a link between pancreatic activity and the autonomic nervous system and is also found in brain. Finally, pancreatic D cells produce *somatostatin*, which inhibits both insulin and glucagon when produced in the pancreas, but is also released from the hypothalamus as an inhibitor of STH in the pituitary.

The Thyroid Gland

The hormones released from the thyroid (tyrosine-based hormones) *thyroxin* and *triiodothyronine* (*T4 and T3*) need iodine for their synthesis and are transported protein bound to receptors into almost all cells of the organism, where T4 is changed into T3. This increases basic metabolism in interaction with the steroids cortisol and aldosterone as well as with the catecholamines leading to sympathetic stimulation of heart rate, temperature, and general physiological arousal.

The Adrenal Medulla

The *catecholamines noradrenalin, adrenalin, and dopamine,* released from the adrenal medulla (and noradrenine additionally from sympathetic neurons) *are* also synthesized from the amino acid tyrosine and structurally similar to each other. Besides their sympathetic action on circulation and metabolism in the periphery, they are synthesized in neurons of the brain where they act as neurotransmitters (*see* Hypothalamus) and neuromodulators by their effects on the hypothalamic releasing and inhibiting hormones of the pituitary (see Figure 1).

The Adrenal Cortex

Similarly, the steroids *cortisol and aldosterone*, produced in the adrenal cortex by stimulation of ACTH from the pituitary and the gonadal steroids *estrogen and testosterone* stimulated by LH and FSH respectively (see Figure 1) have many different functions in reproduction and metabolism, which, however, have been described in the article Hypothalamic-Pituitary-Adrenal Axis, Psychobiology of.

Most hormones secreted from peripheral glands also have receptors in the brain. This refers to the steroids from the adrenal cortex, thyroid hormones, the peptides of the pituitary, melatonin from the pineal gland, and insulin secreted from the pancreas. Steroids from plasma can pass the blood–brain barrier due to their lipophilic structure, some of the peptides released from the pituitary may reach the brain via receptors at the circumventricular regions (locations not surrounded by the blood–brain barrier, which cannot be penetrated by peptides) This means that besides their functions in metabolism, circulation, reproduction, or their role as releasers or inhibitors of other hormones, they can modify mental functions and behavior. There is an abundant bulk of research concerning the role of hormones in behavioral, emotional, and cognitive responses to stress, in personality traits, or in psychiatric diseases, published in specialty Journals like *Psychoneuroendocrinology*.

Neuropeptides, Tissue Peptides, and Neurosteroids

Besides the peptides listed as hormones from the neuropituitary, ADH and OXT, there are *neuropeptides* produced in neurons of the hypothalamus acting as releasers or inhibitors of the pituitary hormones (CRF, GnRF, TRF, GHRF) (see Figure 1). Of these, the *corticotropin releasing factor* (*CRF*) deserves special interest, because apart from being part of the HPA axis by releasing proopiomelanocortin (POMC) in the pituitary from which ACTH, α-MSH, and the β-endorphin are derived, CRF has direct effects on sympathetic activity and the adrenal medulla thus being responsible for release of catecholamines. Moreover, it reduces food and water intake and increases locomotion and anxiety and is therefore an essential hormone in stress responses.

Similarly multiple functions are exerted by the inhibiting hormone of STH, *somatostatin (growth hormone inhibiting factor GHIF)* an antagonist of the releasing factor GHRF depicted in Figure 1 Somatostatin also inhibits TSH and ACTH in the pituitary, renin in the kidneys, a number of gastric peptides, and the pancreatic peptides described above, but also inhibits release of acetylcholine in the brain and hence electroencephalographic (EEG) activity (Klinke and Silbernagel, 2001: p. 466).

There is a large number of additional brain-derived peptides involved in several central nervous functions, like α-melanotropin (α-MSH, responsible for reduction of food intake) and β-endorphin (reduction of pain), both released by CRF in the

hypothalamus (see above), or the enkephalins (also acting as endogenous opioids), and many others responsible for nerve growth and neuroprotection. But, in addition, an ever growing number of the so-called *tissue hormones* produced in tissues of the gut, lung, liver, heart, kidney, and adipose tissue, has been detected, which partly act on the surrounding tissue (paracrine action) or by stimulation and inhibition of their own synthesis and release (autocrine action). Many of them have additionally been found in the brain, predominantly in the hypothalamus regulating, for instance, hunger and satiety (e.g., leptin, neuropeptide Y (NPY)). Also substance P and the vasoactive intestinal polypeptide (VIP) are produced in neurons, acting as neurotransmitters for stimulation or inhibition of gastrointestinal secretion or muscle contractions (substance P, VIP). Even neuropeptides, which are only produced in the gut and not in neurons (cholecystokinin (CCK) and neurotensin (NT)) may, in addition to their role in digestion, have psychological effects like regulation of feeding and appetite. Several of these act as cotransmitters (neuromodulators, i.e., enhancing or reducing transmitter activity). For example, NPY is a cotransmitter of noradrenaline, adrenalin, and GABA; CCK of GABA; substance P and VIP of acetylcholine.

In addition to neuropeptides, the so-called *neuroactive steroids* are produced in the brain. They are either synthesized in neurons of the brain or enter the brain as metabolites of adrenocortical or gonadal steroids related to each other as depicted in Figure 2. Pregnenolone, the general precursor of the four major steroids of the adrenal cortex as well as dehydroepiandrosterone (DHEA) and derivatives of progesterone have been identified as neuroactive steroids. Their role in neuroactivity is modulation of neuronal excitability, for instance, by potentiating or reducing GABA-receptor mediated activity. So, for example, two derivatives of progesterone of very similar structure act antagonistically on the GABA A receptor and have been found to be increased or decreased in depression, respectively (Schüle et al., 2011). Thus, these compounds have been used therapeutically in the treatment of depression and anxiety. Like glandular steroids, neurosteroids act on intracellular receptors and can, therefore, also regulate gene expression (Dubrovsky, 2006).

Feedback Systems

Hormones, like many other systems of the body governed by the principle of homeostasis (e.g., blood glucose, body temperature), are characterized by *feedback* processes. The most popular one is that peripheral levels of a hormone signal to the site of synthesis that further production should be reduced (negative feedback) and vice versa (positive feedback). This is the case with paracrine actions in tissue hormones in somatic cells as well as with transmitters in the brain, where reduction or increase of hormone release are reflected not only by regulation of synthesis and release, but also by up- and downregulation of respective receptors (low levels → upregulation = increase in number of receptors, high levels → downregulation = reduction in number of receptors, *see* Neurotransmitters). This principle also applies to the feedback loops depicted in Figure 1.

In Figure 1 the three major systems organized along a four step axis: the hypothalamo–pituitary–adrenal (HPA) axis (*see* Hypothalamic-Pituitary-Adrenal Axis, Psychobiology of), the hypothalamo–pituitary–gonadal (HPG) axis, and the hypothalamo–pituitary–thyroid (HPT) axis were depicted. In addition, the regulation of the two hormones of the posterior lobe of the pituitary, adiuretin and oxytocin, were included, which do not act on a subordinate gland, but are also governed by releasing and inhibiting hormones from the hypothalamus. The reason for calling the system as a four step system is that neurotransmitters from other parts of the brain, mostly from the limbic system, have been identified as stimulating and inhibiting factors of the hypothalamus, which gave rise to change of names into LHPA-, LHPG- and LHPT-axes. For reasons of space, the inhibiting factors of prolactin (prolactostatin (PIF)) and growth hormone (somatostatin (SIH)) produced in the hypothalamus have not been illustrated. As shown in the figure, feedback loops can be observed from the pituitary level to the hypothalamus (ultrashort feedback), from the peripheral gland to the stimulating hormones from the pituitary (short feedback), and directly from plasma levels of the peripheral hormones to the hypothalamus. Feedback principles like these are used for diagnostic tests assessing disturbances in hormone release as in the case of the dexamethasone or the dexamethasone–CRH test used for testing the feedback of cortisol responses to CRF sensitivity (*see* Hypothalamic-Pituitary-Adrenal Axis, Psychobiology of).

Rhythms

In addition to this demand adapted regulation, most hormones are also governed by rhythmic release concerning amplitude of levels as well as number of pulsatile secretions. These may follow an ultradian, circadian, or lunar pattern. *Ultradian cycles* refer to changes of several times within a day. Pulsatile rhythms of secretion of about 12–15 min are reported for insulin, a rhythm of about 90 min (called rest activity cycle, RAC, characteristic of many systems), for instance, applies to GnRF releasing LH, which follows at the same 90 min intervals.

This rhythm may also exist in addition for hormones governed by *circadian cycles* like ACTH, cortisol, or melatonin as well as to pituitary peptides like β-endorphins, which change according to a 24 h (circadian, day–night) rhythm, not necessarily depending on sleep–waking stages. These cycles may be synchronized or desynchronized by external stimuli-like daylight or temperature. Other rhythms are rather coupled to patterns of sleep like the pituitary peptides STH, PRL, and TSH as well as LH and FSH. Acrophases (highest concentrations) for ACTH, cortisol, and β-endorphins are observed between 6 and 9 a.m. and for the sleep dependent hormones between midnight and 2 a.m.

A *lunar cycle* is represented by the hormones of the gonadal axis, where estradiol and in consequence LH are low during the menstrual phase, rise in the follicular phase, and have their peak at ovulation on day 12–14 of the menstrual cycle. Estradiol releases LH, and drops much more slowly than LH during the luteal phase, when progesterone released from the corpus luteum rises to higher levels than estradiol.

But even longer periods of several months or years organized according to seasons like the gonadal hormones in animals, or rhythms depending on the phase of life are

Figure 2 Relationships between steroid hormones of the HPA axis (left) and the HPG axis (right). Modified from Netter, P., 2008. Neurochemische und endokrine Systeme in der experimentellen Emotionsforschung: Forschungsansätze und Grundlagen. In: Janke, W., Schmidt-Duffy, M., Debus, G. (Eds.), Experimentelle Emotionsforschung. Pabst Science Publishers, Lengerich, Berlin, p. 628.

observed: E.g. STH and testosterone both have their acrophase around 20 years of age, STH decreasing thereafter, while testosterone only drops at the age of about 40–50 in males. In pregnancy, extra rhythms are determined by hormones produced in the placenta, where human chorionic gonadotropin (HCG) shows a steep rise until week 6 of gestation (which can be used as a test of pregnancy in urine), while estradiol and progesterone as well as human placental lactogen (HPL) start rising from about week 12 to the end of gestation. Disturbances of these rhythms represent symptoms of certain diseases, like depression or infertility. Even more relevant are disturbances in amplitude of hormone production, since in practically all major hormones hyper- as well as hypoactivity can cause specific endocrinological diseases.

Interactions between Hormone Systems

It must be pointed out that the hormones representing specific functions in metabolism, reproduction, and behavior are heavily interrelated with each other and with additional hormones and transmitters. Interactions between the two systems most relevant for behavior, the HPA and the GPA axes, may be selected for demonstrating that hormones may not only be functionally, but also structurally related. Figure 2 demonstrates structural relationships between the two major products of the HPA axis, the glucocorticoid cortisol and the mineralocorticoid aldosterone, and the two final compounds of the GPA axis, the female hormone, estradiol and the male hormone, testosterone.

Belonging to the class of steroids, they are all derived from the basic molecule cholesterol and end up in different metabolites in urine, which can be used for assessing endocrine effects from experimental manipulations or endocrine diseases. The similarity of action of the steroids may be explained by the fact that progesterone, the hormone of the corpus luteum, and adrenal cortex can be transformed into practically all of the final hormones (see Figure 2). Similarly, testosterone (T) can be transformed into estradiol (E2) in fatty tissue, which is relevant for the observation that older males may develop female breasts (the reverse process (T into E2) is still questioned).

Yet, when considering the functional interaction of the HPA and HPG axes, they may exhibit antagonistic properties This is due to (1) direct inhibitory effects of CRH on GnRF, (2) an inhibitory action of cortisol on GnRF, FSH, and LH, (3) an inhibitory effect of the CRH-stimulated catecholamines noradrenaline and adrenalin on GnRF, and (4) an inhibitory effect of CRH stimulated endogenous opiates on GnRF. Furthermore, 5-HT stimulates release of CRF, but inhibits release of GnRF. This becomes evident by increase of cortisol (C) and suppressions of testosterone (T), when serotonergic substances are applied, which may explain the antagonistic responses of cortisol and testosterone to controllable and uncontrollable stressors (controllable stress: decrease or no change of C and increase of T, uncontrollable stress: increase of C and decrease of T, (Henry, 1986)).

Another example of interaction between two neuroendocrine systems is the mutual influence of the adrenal medulla and adrenal cortex: cortisol locally enhances the synthesis of noradrenaline and adrenalin in the adrenal medulla by stimulating three of the enzymes involved in transforming the amino acid tyrosin across dopa and dopamine into noradrenaline, which is finally converted into adrenalin, and vice versa, the catecholamines act on cortisol via stimulation of the HPA axis (see Figure 1).

Table 3 Principles of transmitter challenge tests, classes of substances used, and corresponding hormone responses

Principle of action	*Serotonin (5-HT)*		*Dopamin (DA)*		*Noradrenaline (NE)*	
	Substance (example)	*Hormone response*	*Substance (example)*	*Hormone response*	*Substance (example)*	*Hormone response*
Precursor for synthesis	L-Tryptophan	PRL↑ Cortisol (↑) GH (↑)	L-Dopa	(PRL ↓)		
Blockade of synthesis	Tryptophan depletion	PRL ↓	AMPT	(HVA ↓)		
Release	D-Fenfluramine	PRL ↑ Cortisol (↑)	Amphetamine	(PRL ↓)	Reserpine	?
Reuptake inhibition	Citalopram, Fluoxetine	Cortisol ↑	Mazindole	(PRL ↑)!!* GH ↑	Reboxetine	Cort ↑ GH ↑
Receptor agonism	Ipsapirone 5 – HT_{1a} receptor	Cortisol ↑	BromocriptineD_2 receptor Apomorphine D_2D_1 receptor	PRL ↓ GH (↑) PRL ↓ GH ↑	α_2:Clonidine	TSH ↑ GH ↑
Receptor antagonism	Cyproheptadine – HT_{2a} receptor	Cortisol ↓	Fluphenazine D_2D_1 receptor	PRL ↑		

!!* = dopamine increase would normally suppress PRL, here: opposite effect, PRL = prolactin, Cort = cortisol, GH = growth hormone, HVA = homovanillic acid, AMPT = α-methylparatyrosin, TSH = thyroid stimulating hormone, 5-HT = serotonin, D = dopamine; ? = no hormone response confirmed, weak or contradictory response or response only with higher doses, ↑ increase, ↓ decrease.
Modified from Netter, P., 2008. Neurochemische und endokrine Systeme in der experimentellen Emotionsforschung: Forschungsansätze und Grundlagen. In: Janke, W., Schmidt-Duffy, M., Debus, G., (Eds.), Experimentelle Emotionsforschung, Pabst Science Publishers, Lengerich, Berlin, p. 625.

Hormones as Indicators of Neurotransmitter and Hypothalamic Activity

The catecholamines produced in the adrenal medulla mentioned above, do not only act as hormones in the periphery, but are also produced in neurons in the brain stimulating or inhibiting synthesis or release of hypothalamic and pituitary hormones as shown in Figure 1. Therefore, hormones can also be used as indicators of transmitter activity by the application of the so-called *neurotransmitter challenge tests:* a specific pharmacological substance acting on the noradrenergic, dopaminergic, or serotonergic system is applied, which either interferes with synthesis, release, receptors, or metabolism of that particular transmitter, and specific hormone responses on the pituitary level (PRL, GH, TSH) or on the level of glandular responses (mostly cortisol) can be measured in plasma or saliva (in urine only after a delay of several hours, but contaminated by different intermediate effects). Hormone responses have to be measured before and several times after the challenge. Parameters of hormone responses are either measures of amplitude of hormone released (area under the response curve or highest difference from baseline) or parameters of slope of increase and decline (see Reuter et al., 2002) or time of onset of the hormone response. Challenge tests have been used in clinical as well as in experimental research to test for disturbances and individual differences in sensitivity of certain neurotransmitter systems, which are particularly relevant in psychiatric diseases, since there is no direct access to the transmitter systems in the brain in humans. Examples of challenge tests with their substances for testing transmitter activity and corresponding hormone responses are listed in Table 3.

As can be seen from Table 3, tests may refer to synthesis, release, reuptake, and receptor agonistic and antagonistic effects demonstrating different levels of interference with the specific transmitter. Unfortunately, not all hormones suitable as possible indicators of transmitter actions have been tested for all transmitter principles of action and for all transmitter systems, and even, if so, their effects on hormones may not be positively correlated to each other (see e.g., receptor agonists of dopamine). This may be due to the fact that pharmacological challenges by drugs may affect rate of synthesis, rate of release, sensitivity and number of receptors, sensitivity of the transporter (responsible for reuptake of the remaining transmitter from the synaptic cleft after binding of the transmitter to the postsynaptic receptors), and enzymatic catabolism of the transmitter. So, unfortunately, when monitoring a hormone response, one is never sure to which of these processes the hormone response may be attributable. This is even more the case when psychological responses, like performance, emotional reactions, or social behavior are the target of interests, because then the challenge substance itself, the hormone elicited, and the genetic and personality dispositions of the person may be responsible for variations in hormone responses. Yet, challenge tests have revealed insight into the relevance of serotonin, dopamine, and noradrenaline for personality related transmitter responsitivity and psychiatric diseases, most of which are based on disturbances of transmitter systems.

Similarly, hormones of the pituitary can be tested by application of respective hypothalamic stimulating hormones. For example, TRH application can indicate either increased sensitivity of TSH represented by elevated TSH responses demonstrating hypofunction of the thyroid hormones (observed with the disease of myxedema) or, vice versa, reduced TSH responses indicating high thyroxin and T3 levels observed in hyperfunction of the thyroid as observed with Morbus Basedow (an autoimmune disease). By a more indirect

pathway, the application of the corticosteroid dexamethasone can indicate a disturbed feedback loop of the HPA axis (*see* Hypothalamic-Pituitary-Adrenal Axis, Psychobiology of). Many more tests like this make use of the stimulation and feedback loops discussed above.

Abstract

Neuroesthetics is a subfield of cognitive neuroscience that studies the biological mechanisms and psychological processes evoked in the creator or the spectator when adopting an esthetic orientation toward an artistic or nonartistic object in the course of interacting with it. These psychological processes are related to perception, cognition, emotion, evaluation, social, and contextual aspects. Here, we outline the scope of neuroesthetics and summarize its historical background. We thereafter sketch three current approaches to neuroesthetics, and examine recent developments in three areas: emotions, context, and expertise. We finish with an exploration of the potential for future inquiry in neuroesthetics.

Introduction: Aims and Scope of Neuroesthetics

Stated briefly, neuroesthetics is a scientific field that aims to understand the neural mechanisms that underlie esthetic behavior. Despite possessing the virtue of conciseness, such a characterization is unsatisfactory because it ignores important conceptual subtleties. First, neuroesthetics can properly be viewed as a subfield of cognitive neuroscience. As such, it combines neuroscience techniques and cognitive science methods (Gazzaniga, 1984), bringing the cognitive and neural levels of explanation of behavior together into a single approach (Churchland and Sejnowski, 1988). Second, rather than regarding esthetics as an abstract concept, neuroesthetics conceives it as a form of human cognition, and thus, it focuses on particular esthetic experiences, esthetic creation, esthetic preference, esthetic choice, and so on. Third, neuroesthetics assumes that such forms of esthetic cognition arise from the interaction of perceptual, emotional, and evaluative processes with social and contextual factors. In fact, understanding such interaction is one of the field's main goals. Fourth, the creation and appreciation of artworks are within the scope of neuroesthetics. However, just as the field of esthetics is concerned with other objects in addition to artworks, so is neuroesthetics. To understand the biological underpinnings of the human capacity for art production and appreciation is the goal of the cognitive neuroscience of art (Seeley, 2011). Both fields overlap, but they are not identical (**Figure 1**). Neuroesthetics deals with a broader set of objects of esthetic interest, such as utensils, commodities, or graphic and industrial designs. The cognitive neuroscience of art, in turn, sets out to understand a broader set of issues related to art, beyond the purely esthetic ones, such as grasping the meaning of an artwork, or understanding its significance in its art-historical or art-critical contexts. Both fields overlap when attempting to understand how esthetic qualities are used to produce and appreciate the content and form of an artwork.

Neuroesthetics, thus, is not concerned with a particular class of objects. Rather, it focuses on a certain kind of way objects can be experienced when people approach them with an esthetic orientation (Cupchik, 1992). From this perspective, neuroesthetics can be conceived as the study of the biological mechanisms and psychological processes evoked in the creator or the spectator when adopting an esthetic orientation toward an artistic or nonartistic object in the course of interacting with it. These psychological processes and their biological underpinnings are related to perception, cognition, emotion, evaluation, as well as to social and contextual aspects (Skov and Vartanian, 2009).

Figure 1 Representation of the relation between neuroesthetics and the cognitive neuroscience of art and their research topics.

Historical Background of Neuroesthetics

The term neuroesthetics was coined at the end of the twentieth century (Zeki, 1999). Scientists and humanists, however, have been interested in the neurobiological substrates of esthetic experience for at least 250 years. Burke (1757) argued that such experiences did not rely on specialized biological mechanisms, that the beautiful and the sublime were mediated by the same physiological mechanisms as common emotions like love and fear. Objects, landscapes, and other people were regarded as beautiful – he believed – because they caused the same relaxation of the nerves as the emotions of love or tenderness. Objects and events that agitated and tensed the nerves, in a similar way to pain, fear, or terror, were experienced as sublime. Two main issues became the focus of scientists' attention during the second half of the nineteenth century. First, the relation between pleasure, pain, and esthetics was extensively discussed. Whereas Marshall (1893) went as far as considering psychological esthetics as a branch of hedonics, and Allen (1877) made the bodily processes of pain and pleasure the cornerstone of his *Physiological Aesthetics*, James (1890) believed that what defined esthetic feelings was precisely the absence of the physiological component of common emotions. Second, the issue of the adaptive value of art and esthetics spurred hypothetical scenarios – based on natural selection or sexual selection – that hoped to explain the origin and evolution of art and esthetics (Darwin, 1871/1998).

It was Fechner's (1876) *Vorschule der Aesthetik*, however, that marked the inception of an empirical science of esthetics. Fechner developed a suite of basic principles that aimed to explain esthetic appreciation. His methodological innovations were, nevertheless, his most lasting and influential contributions. It was he who introduced the now familiar practice of measuring the responses of samples of participants, representative of certain populations, to large numbers of objects. He devised three main methods to elicit his participants' responses: the method of choice, the method of production, and the method of use. The first of these became dominant in the experimental psychology of esthetics, while the use of the other two declined, to the point that most of what empirical esthetics has shown about people's esthetic experience is based on participants' choices or ratings (Westphal-Fitch et al., 2013).

During the twentieth century, the incipient neuroesthetics explored the effects of brain lesions and neurological illnesses on artistic creation. The focus of much of this work was the relation between aphasia and music, painting, and literature (Alajouanine, 1948). Because such reports often described artistic change in single cases after the onset of lesions or illnesses in ambiguous or imprecise terms, it was not easy to arrive at meaningful conclusions or to identify general trends (Chatterjee, 2004). The neuroimaging techniques that became available toward the end of the twentieth century allowed scientists to explore their hypothesis experimentally in controlled situations, with the participation of healthy subjects, and to correlate the appreciation and enjoyment of music, painting, architecture, sculpture, and dance, with neural activity.

Approaches to Neuroesthetics

The biological underpinnings of esthetic behavior have been explored using a broad variety of methods. One approach, which Chatterjee (2011) refers to as parallelism, aims to illustrate how artists throughout the centuries have devised techniques and used resources that catch the attention of spectators, interest them, and appeal to them by engaging certain neural processes related with reward and arousal (Zeki, 1999; Ramachandran and Hirstein, 1999).

Relying on clinical cases, other researchers have described the impact of brain damage and neural degeneration on the production and appreciation of art and on esthetic experiences. This second approach has shown that artists are vulnerable to the same visual, motor, auditory, and cognitive neuropsychological deficits that affect other people, despite their proficient perceptual and motor skills, though they manifest these deficits in strikingly eloquent ways (Chatterjee, 2004). Most artists suffering from neurological disorders continue to be artistically motivated, productive, and expressive after the onset of their condition (Zaidel, 2005). There usually is, however, a noticeable change in the work of most artists who have suffered a stroke. Those sufferings from neurodegenerative disorders, such as Alzheimer's disease, seem to gradually loose the ability to represent the world with precision, but are able to make use of color and form in esthetically appealing ways (Miller and Hou, 2004). Neurological disorders can also affect esthetic appreciation. Depending on the nature of the disorder, people might have difficulties perceiving objects' particular sensory features, recognizing or recollecting them, or engaging emotionally with them. In most cases, however, patients are capable of recognizing and experiencing the esthetic qualities of art and other objects in a meaningful and consistent way (Halpern and O'Connor, 2013). Neurological studies suggest that esthetic preference is surprisingly resilient in the face of neurological conditions, and argue against the existence of specialized brain mechanisms underlying the experience of art (Zaidel, 2005).

The third approach to neuroesthetics noted by Chatterjee (2011) is experimental neuroesthetics. This approach has mostly – though not exclusively – used neuroimaging methods to study the role of different brain regions in esthetic experiences. When applied to neuroesthetics, such methods have usually required participants to judge the beauty, the attractiveness or the appeal of stimuli presented to them, or to state how much they like or prefer them, while their brain activity is being registered. Neuroimaging studies have revealed that neural activity in the reward circuit is a key component of esthetic experience, but the picture is a complex one. Positive or negative esthetic experiences are the result of a complex interplay of neural processes related to reward representation, prediction and anticipation, affective self-monitoring, emotions, and the generation of pleasure, that take place in cortical (i.e., anterior cingulate, orbitofrontal, and ventromedial prefrontal) and subcortical (i.e., caudate nucleus, substantia nigra, and nucleus accumbens) regions, as well as some of the regulators of this circuit (i.e., amygdala, thalamus, and hippocampus) (Cupchik et al., 2009; Harvey et al., 2010; Ishizu

and Zeki, 2013; Kirk et al., 2009b; Lacey et al., 2011; Salimpoor et al., 2011; Salimpoor et al., 2013; Vartanian and Goel, 2004).

However, neuroimaging studies have shown that there is more to esthetic appreciation than pleasure and reward (Nadal and Pearce, 2011). Such studies have also shown that esthetic experiences involve an enhancement of activity in cortical regions related to sensory processing. These regions include the bilateral fusiform gyri, angular gyrus, and the superior parietal cortex in visual esthetic experiences (Cela-Conde et al., 2009; Cupchik et al., 2009; Lengger et al., 2007; Vartanian and Goel, 2004), primary and secondary auditory cortices during musical esthetic experiences (Brown et al., 2004; Salimpoor et al., 2013), and the extrastriate body area of the occipital cortex and the ventral premotor cortex during esthetic appreciation of dance (Calvo-Merino et al., 2010). The analysis of functional connectivity suggests that this enhancement of perceptual processes owes primarily to the effects of attention (Lacey et al., 2011). Finally, viewing artworks or designs that are liked, found appealing, or beautiful, is also accompanied by an increase in the activity throughout a network of cortical regions related to evaluative judgment, the allocation of attentional resources, and the retrieval of information from memory to contextualize the stimuli and judgment, including the dorsolateral and ventrolateral prefrontal cortex, anterior medial prefrontal cortex, temporal pole, posterior cingulate cortex, and precuneus (Cela-Conde et al., 2004; Cupchik et al., 2009; Jacobsen et al., 2006; Lengger et al., 2007).

Main Current Research Topics

Emotion

What are the biological mechanisms that underlie the affective and emotional aspects of esthetic experience? What does it mean, in biological terms, to be moved by such esthetic qualities as beauty, grace, or sublimity? These questions can be answered only in part when there still is much debate surrounding such fundamental issues as whether there are specific esthetic emotions, whether esthetic experiences can involve common emotions – such as joy, anger, or sadness – or whether emotion is even a necessary ingredient of esthetic experience.

Is there such a thing as esthetic emotions? Some researchers have argued that there are indeed certain classes of emotions that are intrinsic to esthetic experiences. Konecni (2005), for instance, conceived esthetic awe as a specific esthetic emotion, a prototypical response to the sublime. In his view "It is the most pronounced, the ultimate, esthetic response, in all ways similar to the fundamental emotions" (Konecni, 2005: p. 31). Keltner and Haidt (2003), in contrast, suggested that awe might accompany a variety of experiences, including the appreciation of art, though only under certain circumstances. It is art's reliance on depictions of vastness, exceptional actions or moments, or just its sheer size – Keltner and Haidt (2003) argue – that makes it possible to produce profoundly moving emotions of awe that go beyond mere esthetic pleasure.

Lazarus (1991) has espoused the opposite view, namely, that there are no exclusive or prototypical esthetic emotions. In his view, an 'esthetic emotion' is a common emotion experienced in response to art or any other object of esthetic contemplation. Thus, esthetic emotions are elicited by portrayals of emotional content to which people can relate. The strength of such esthetic emotion depends fundamentally on the extent to which spectators identify with the representation and the personal significance of the depicted content. Emphasizing the role of appraisals, Silvia (2006) has also argued that a broad range of common emotions can be a part of an esthetic experience. Appraisals constitute the key mechanism underlying the elicitation of all kinds of emotions in response to objects of esthetic contemplation, and specifically to artworks. Interest, confusion, and surprise, that is to say, the knowledge emotions, are elicited by appraisals in terms of novelty, complexity, familiarity, and coping potential. Appraisals of goal-incongruence, intentionality, harmfulness, or contamination can lead to such hostile emotions as anger, disgust, or contempt. People can also feel self-conscious emotions, such as pride, shame, and embarrassment, while engaging with art. They are related to appraising the congruence of artworks with one's own values, self-image, or goals, the degree personal responsibility, and the consistency with one's standards (Silvia, 2009).

Scherer (2004), however, argued that esthetic emotions – understood as common emotions experienced in response to art – differ from utilitarian emotions, that is to say, common emotions experienced in response to physical and social events occurring outside any artistic context. Esthetic emotions lack the appraisals of goal relevance and coping potential, common to utilitarian emotions: "an aesthetic experience is one that is not triggered by concerns with the relevance of a perception to my bodily needs, my social values, or my current goals or plans, nor with how well I can cope with the situation, but one where the appreciation of the intrinsic qualities of a piece of visual art or a piece of music is of paramount importance" (Scherer, 2004: p. 244). Although esthetic emotions can come with strong phenomenological feelings, they exhibit weaker physiological manifestations than utilitarian emotions, and they lack the arousal and action-oriented responses observed in the latter: when physiological responses – in the form of chills, shivers, or moist eyes – accompany esthetic emotions, they are not aimed at preparing the organism for any specific adaptive action.

Finally, others have maintained that the emotional facet of esthetic experiences is dual. It is not only the content and its personal significance, that drives the emotional response in an esthetic episode (Frijda, 1986; Tan, 2000). The response to Scherer's (2004) intrinsic qualities constitutes a separate and discrete emotional aspect of the esthetic experience. Thus, the represented content arouses one kind of emotions, called 'complementing emotions' (Frijda, 1986) or 'represented emotions' (Tan, 2000). These could be any of the common emotions. In addition, the style, the medium, or the process itself of achieving understanding of the artwork or the object, can elicit a different sort of emotions, called 'responding emotions' (Frijda, 1986) or 'artifact emotions' (Tan, 2000). The enormous expressive potential of art and esthetics allows multiple combinations of these classes of emotions. Artists throughout the centuries have, in fact, exploited the effects of

the incongruence of emotions elicited by content and style (Eco, 2007). Some Hellenistic artists, for instance, abandoned idealist representations in favor of the accurate depiction of profane and everyday topics, which sometimes involved portraying the visible manifestations of old age, violence, or suffering (Stokstad and Cothren, 2011) (**Figure 2**).

Neuroesthetics has contributed to this discussion, mainly through the use of neuroimaging and psychophysiological techniques, in two different ways. First, it has provided psychologists with a new level of analysis. Second, it has allowed asking fascinating new questions. For instance, Skov (2010) sought to characterize the neural mechanisms that enable us to deal with the aforementioned conflicting emotional responses elicited by images' content and formal qualities. He showed participants a series of 300 pleasant, neutral, and unpleasant photographs from the International Affective Picture System, while in the functional magnetic resonance imaging (fMRI) scanner, and asked them to rate them as beautiful, neutral, or ugly. His comparison of brain activity while viewing images rated as beautiful and ugly, regardless of their affective valence, confirmed previous studies that had revealed the involvement of perceptual processing (i.e., superior occipital gyrus, fusiform gyrus, among other regions), reward processing (i.e., orbitofrontal cortex, cingulate cortex), and executive processing (i.e., several prefrontal regions). By examining the interaction between the affective valence of the images' content and participants' ratings, he identified brain regions whose activity was different when participants rated unpleasant images as beautiful and when they rated pleasant images as beautiful. This comparison revealed activity in additional regions of the brain, especially in high-level perceptual processing areas, such as the inferior and superior temporal sulci, and certain regions related with reward, such as the caudate nucleus. These results suggest that specific perceptual and affective mechanisms come into play when we appreciate the esthetic qualities of stimuli depicting emotionally negative content.

Figure 2 Statue of an old market woman (first century AD). She constitutes the opposite of the composed and ideally represented beauty of the Greek Classical period. Her dropped lower jaw, unsteady gait, foggy gaze, and indifference toward her exposed breast, suggest she might be a debauched Dyonisian follower on her way to an offering. Technically, however, the statue constitutes a masterful rendering of complex textures and forms that create the striking contrasts of light and shadow that characterize much of Hellenistic sculpture (Stokstad and Cothren, 2011). Original height: 49 5/8 in. (125.98 cm). The Metropolitan Museum of Art, Rogers Fund, 1909 (09.39). Image © The Metropolitan Museum of Art. Reprinted with permission.

Salimpoor et al.'s (2011, 2013) studies on the neural underpinnings of positive emotional responses to music constitute excellent examples of how neuroesthetics can open new avenues of inquiry. Salimpoor et al. (2011) examined the release of dopamine in different brain regions while people listened to musical pieces that they either did or did not deeply enjoy with a special interest in participants' arousal peaks. Their study revealed an unforeseen functional dissociation. Whereas the caudate was more active during the anticipation of peak emotional experiences, the actual experiences were associated with dopaminergic activity in the nucleus accumbens, showing how the emotional experience of music is mediated by two distinct anatomical pathways that play two different, but complementary, roles in anticipating and generating pleasurable feelings. But how is this positive emotional response tied into the overall esthetic experience? Salimpoor et al. (2013) subsequently used a bidding paradigm, in which participants were asked to listen to unfamiliar fragments of music and allocate amounts of money to listen to them again if they wished. The degree of activity in the nucleus accumbens and an increase in functional connectivity between this region and the auditory cortex, the amygdala, and the ventromedial prefrontal cortex, predicted the amount of money participants were willing to pay to listen to their preferred fragments again (**Figure 3**). These results attest to the importance of the interactions among brain regions involved in reward, sensory processing, and valuation in the generation of the esthetic experience.

Context

With *Fountain* (1917), Marcel Duchamp revolutionized the debate about what constitutes an artwork, and attempted to demonstrate that esthetic qualities could not be part of necessary criteria (**Figure 4**). However, even when his readymade aimed to divorce esthetics from art, some critics were unable to detach themselves from their esthetic orientation toward artworks, believing that "Duchamp was drawing attention to the white gleaming beauty of the urinal" (Danto, 1997), and even stating that "A lovely form has been revealed, freed from its functional purpose, there a man has clearly made an esthetic contribution" (Danto, 1997). A fundamental question arises, thus: what are the contextual conditions that foster such esthetic admiration for everyday objects whose esthetic qualities go otherwise unnoticed?

Figure 3 Changes in NAcc functional connectivity associated with increasing desirability of music. (a) Partial least-squares analysis revealed robust increases in connectivity between the nucleus accumbens (NAcc) and other subcortical and cortical regions when individuals hear music they consider highly desirable, compared with music they do not want to hear again. The boxes show changes in correlation as a function of amount bid between the NAcc and each region. A subset of these regions (shown in panel a) overlap with areas that are recruited during music listening compared with rest (panel b). These areas show equally high activity during all music valuation conditions compared with rest (panel c), but their interactions with the NAcc increase as items become more desirable. The conditions under which certain contextual features modulate neural activity underlying esthetic preference are, in fact, a major topic for neuroesthetics. Several studies have shown that personal attitude toward the object presented and beliefs about it have strong effects. Cupchik et al. (2009) demonstrated that people's orientation toward paintings modulated brain activity associated with esthetic preference. They asked participants to focus on the artworks with an esthetic orientation, attending to their esthetic experiences and the works' esthetic qualities, or to view them merely to obtain information from them and take note mostly of the depicted content. The esthetic orientation led to a greater activity in prefrontal brain regions, suggesting a greater degree of cognitive control. The pragmatic orientation, in contrast, was related to an increase in the activity of occipital regions, suggesting an enhancement of perceptual processes. These results show how certain parts of the network of brain regions involved in computing esthetic preference are modulated by the attitude with which we approach an object.

Kirk et al. (2009a) showed how different semantic contexts, which prompted different expectations on behalf of the participants, had a modulating effect on the activity of certain brain regions involved in esthetic appreciation. Participants viewed a series of abstract images while in the fMRI scanner. They were led to believe that some of these images, which were accompanied by the label 'gallery,' were reproductions of artworks exhibited in a renowned gallery. They were told that the other images, presented with the label 'computer,'

had been created by the experimenters using an image editing software. In reality, all stimuli had been created by the experimenters for the experiment. Despite this, participants preferred the images they believed were taken from a gallery more than those they believed were computer generated. Moreover, the authors found that the activity of the medial orbitofrontal cortex, a brain region known to play a key role in the processing of reward value, increased significantly when participants were viewing the images under the gallery-label condition. A similar study was performed by Huang et al. (2011). They asked their participants to view a set of Rembrandt portraits, and led them to believe that some were authentic and others were copies. Their results showed that believing that the images were copies increased the activity in the frontopolar cortex, which in turn modulated activity in the visual cortex, which is consistent with participants' reports that in this condition they had attempted to identify the cues indicating that those portraits were copies. When the portraits were accompanied by the label 'authentic,' activity in the orbitofrontal cortex increased, similarly to Kirk et al. (2009b) finding. This sort of framing-effects appears to influence neural activity as soon as 200 ms after the presentation of the stimuli (Noguchi and Murota, 2013). These studies clearly show how beliefs and expectations generated using semantic framing with simple words, such as 'authentic,' 'fake,' or 'copy,' can influence neural processes related with the affective processes involved in esthetic preference. These contextual effects, however, can be overridden by participants' expertise (Kirk et al., 2011).

Expertise

Understanding how humans acquire, store, and use knowledge is one of the central aims of cognitive science. Because experts excel at these tasks within their own domains, they have attracted the attention of cognitive scientists. Within their particular domain, experts arrive at the best solution faster and more accurately, they are able to select adequate strategies more successfully, they detect features that novices cannot, they represent problems at a deeper level, they have more accurate self-monitoring strategies, and they execute skills with greater automaticity and less effort (Chi, 2006). There are three fundamental reasons why researchers within the field of neuroesthetics have turned to the study of art or esthetic expertise. In the first place, it provides an optimal strategy to understand how art and esthetic knowledge is acquired, organized, and used. Second, it allows understanding how prior knowledge and experience interact with cognitive and affective processes to produce the esthetic experience or to modulate esthetic preference (Leder et al., 2004). Finally, given that expertise and long-term training are related to modifications in brain processes underlying domain-relevant tasks, expertise can be regarded as a 'natural model' of neural plasticity (Münte et al., 2002).

Studies on the neural foundations of expertise in the domains of art and esthetics have yielded four main findings. First, when making judgments about their objects of expertise, experts tend to show greater activity than nonexperts in brain regions related to conceptual association, memory retrieval, and the activation of referential contexts (Kirk et al., 2009a; Wiesmann and Ishai, 2010), illustrating how experts rely to a greater extent on stored knowledge than nonexperts, who rely more on subjective impressions and momentary feelings.

Second, experts in the domains of art and architecture seem to process their objects of expertise with greater 'neural efficiency,' as suggested by a reduced neural activity in certain regions when compared with nonexperts (Berkowitz and Ansari, 2010; Pang et al., 2013). This finding mirrors the decreases in the extent and intensity of brain activation observed when experts in many other domains perform tasks they are specialized in, suggesting that training and practice reduces the extent or intensity of brain activation by increasing neural efficiency, defined as a sharpening of neural responses in task-relevant processing networks (Kelly and Garavan, 2005).

Third, studies have shown that experts are able to filter out the less relevant information for the task at hand. Expert dancers, for instance, rely less than nonexperts on visual information, and emphasize proprioceptive information (Jola et al., 2011). When evaluating their own objects of expertise, musicians, architects, and art experts integrate reward-related processes in a different way to nonexperts, and are able to ignore irrelevant contextual information biasing such processes (Kirk et al., 2009a, 2011; Müller et al., 2010). For instance, Müller et al. (2010) found that, when asked to rate musical stimuli esthetically, laypeople relied on their affective reactions to the stimuli more than experts, who were able to set aside such reactions and focus on the esthetic qualities of the stimuli to a greater degree. Kirk et al. (2011) demonstrated similar emotional regulation in art experts. Whereas monetary sponsorship enhanced laypeople's appreciation of artworks, and increased activity in the ventromedial prefrontal cortex, art experts were not affected by sponsorship. Results showed that, in the case of experts, the dorsolateral prefrontal cortex downregulated activity in the ventromedial prefrontal cortex, suppressing the effects of the monetary favor on the appreciation of art.

Finally, although expertise is by definition domain-specific, experts outperform nonexperts in tasks that are not directly related to their domain of expertise, and several studies have begun exploring the neural underpinnings of these effects. Musicians, for instance, are able to detect small local deviations in foreign language pitch better and earlier, and such ability is related with underlying neural processes related to the categorization of pitch contours (Marques et al., 2007). Electrophysiological data have shown that musicians are also better than nonmusicians at learning linguistic structures, presumably because of their training in segmentation and memory of auditory streams (Francois and Schön, 2011). The application of abilities learned in one domain to a related one has also been observed in the area of visual arts (Pang et al., 2013). This sort of studies suggests that art and music experts transfer their strategies and abilities to nonartistic and nonmusical stimuli.

Future Avenues for Research in Neuroesthetics

Probably, the greatest challenge neuroesthetics facing today is to expand beyond its reliance on neuroimaging and its focus on brain regions involved in esthetic experience. The tools and

methods afforded by cognitive neurogenetics, for instance, could foster a deeper understanding of the biology of esthetic experience below the level of networks of regions, clarifying the role of hormones, neurotransmitters, or genes. Alterations in neurotransmitter function in disorders such as Parkinson's, depression, or anxiety, can have clear effects on value-based decision making in other domains (Ramsøy and Skov, 2010). Increased dopamine levels can interfere with the integration of emotional and cognitive processes, a crucial mechanism underlying decision making in normal conditions. High concentrations of serotonin, on the other hand, can shift choice strategy, from searching for gains to avoiding loss, risk, or ambiguity.

As Green et al. (2008) argued, however, studying genetic variation as a determinant factor of brain function is not only relevant to understanding the origin and development of pathologies. It also holds great potential to clarify healthy cognitive function. In fact, the aforementioned effects linked to certain disorders only reflect the extremes of a continuum of individual variability in naturally occurring neurotransmitter levels. Such variation is, in turn, the result of the interaction between genetic differences among individuals and particular life experiences (Green et al., 2008; Ramsøy and Skov, 2010). Individual differences in specific genes lead to quantifiable differences in the synthesis of proteins. Because genetic variation can occur in genes related to neurotransmitter function, they can produce differences in neurotransmitter synthesis, transport, postsynaptic uptake, presynaptic reuptake, or breakdown. In turn, this sort of variation in molecular function can affect the degree or location of neural activity underlying certain cognitive operations, which might even translate into differences in overt behavior or performance (Green et al., 2008; Ramsøy and Skov, 2010).

Although these facts have been shown for domains unrelated to art or esthetics, they constitute firm grounds for testing hypotheses regarding esthetic appreciation. It is conceivable that genetic imaging could be used in future studies to point to certain genomic variations that are linked to emotional or cognitive processes involved in esthetic appreciation, and even characterize neural connectivity patterns associated with such processes in participants that differ as a function of the underlying genetic variation. Is this a viable direction for research within neuroaesthetics? Will this sort of strategies lead to an integral understanding of the biology of esthetic experience? "Well, we must wait for the future to show" (Woolf, 1930).

Neuroethics: Ethics of Science and Science of Ethics

Pietro Pietrini and Giuseppina Rota, University of Pisa Medical School, Azienda Ospedaliero-Universiaria Pisana, Pisa, Italy

Abstract

Scientific advancements over the last decades have led to powerful tools to investigate the neural underpinnings of mental function as well as to novel strategies to treat brain disorders. These unprecedented acquisitions pose questions that fall far beyond the clinical field itself as they affect also the social, ethical, and law domains. The term *neuroethics* refers to (1) the ethical issues that arise in neuroscientific research and its clinical applications and (2) the study of the neurobiological underpinnings of ethical concepts and moral judgment. In this article, we discuss the main issues comprised within this dual definition of neuroethics.

Introduction

The word *neuroethics* was used for the first time in 1973 by Anneliese A. Pontius, a Harvard neuropsychiatrist, in an article published in the journal *Perceptual and Motor Skills* to describe the negative consequences associated with early walking as an attempt to accelerate motor development in infants (Pontius, 1973). Additional meanings have been associated to this word in the following years. In 1989, for example, the neurologist Ronald Cranford used it to refer to ethical issues in clinical neurology (Cranford, 1989). In 1991, Patricia Churchland defined *neuroethics* as the biological approach to the study of human morality (Churchland, 1991), which can be achieved through modern techniques for the visualization of *in vivo* brain activity.

The birth of neuroethics as a new discipline may be traced back to May 2002. In this year, for the first time, the *New York Times* journalist William Safire used the word *neuroethic*s with its current meaning. In 2002, an important meeting held in San Francisco under the title *Neuroethics: Mapping the Field* gathered scientists and philosophers to discuss ethical issues related to the advancements in the applications of neuroscience (*see* Cognitive Neuroscience; Computational Neuroscience). Since then, the term *neuroethics* has been used to define both ethical issues in neuroscientific research and its clinical applications as well as the investigation of the neural underpinnings and correlates of ethical concepts such as moral decision making and free-will (Roskies, 2002).

In general, this discipline aims to clarify the way neuroscience findings and advances in neuroscientific methods and technology affect society and culture.

The *ethics of neuroscience* focuses primarily on (1) the way research is planned and the procedures that are followed in neuroscience, and (2) the effects and the influence of neuroscientific findings on medical treatments, social policy, the legal system, and so on. The first group of issues includes principles that research in neuroscience should observe, such as following approved protocols, obtaining an informed consent, and respecting autonomy and privacy rights of patients and healthy volunteers. Technological advances make new forms of interventions into the brain available. This, in turn, poses many ethical problems as to whether these practices may alter the personal identity or carry adverse side effects for health and whether they may be considered as morally acceptable in light of their implications for society.

The *neuroscience of ethics* is concerned with the use of neuroscientific methods to investigate topics that have been traditionally the center of philosophical investigations, such as free-will or moral judgment. This area investigates the neurobiological correlates of moral cognition, and specifically the way moral reasoning and decision making are represented in the human brain.

Most topics of investigation of neuroethics have important reverberations and implications for society. For example, is it ethically acceptable to take advantage of drugs to enhance mental and/or physical abilities? Which consequences may have learning that a specific genetic predisposition exposes us to a significantly greater risk of developing a given illness or to manifest aggressive behavior in response to a provocative situation? A deeper understanding of the etiopathology of mental disorders may lead to redefine the notion of free-will, with consequent implications for the concept of personal responsibility in court. How will the ability to predict behavior in a probabilistic way affect society? These and many others are the questions that challenge researchers in neuroethics. In this article, we discuss the main topics that are embraced by neuroethics.

The Ethics of Neuroscience

Over the last decades, novel powerful technologies for brain research have been developed. Modern neuroimaging methodologies, including high-field magnetic resonance imaging (MRI), enable a fine visualization of the morphological and functional architecture of the brain in a noninvasive manner in humans. On a clinical ground, these fine methodologies have made it possible to achieve earlier and more accurate diagnoses, as well as to perform sophisticated interventions, suffice to think of electrode implantation into structures that are deep in the brain or the application of neuroprostheses to restore lost sensory or motor functions. Psychopharmacology research may allow enhancement of individual skills, compensation for congenital or acquired cognitive or affective deficits in impaired individuals, and potentiation of existing skills in healthy population. Although very promising and potentially very useful for the treatment of neurological and psychiatric disorders, these methods raise many ethical issues. Here, we discuss the main ethical aspects related to the distinct domains.

Psychosurgery

In the history of medicine, many interventions on the brain have been devised. In ancient times, for example, holes were drilled into the skull as a means to relieve pain due to hematomas and other neurological accidents. The term *psychosurgery*, that is neurosurgery applied to cure mental disorders, was first introduced to describe a type of brain intervention also known as *prefrontal leucotomy*, which consisted in interrupting the connecting fibers from the prefrontal cortex (*see* Prefrontal Cortex) and other brain areas by sectioning subcortical white matter and by injecting alcohol (Moniz, 1937). In transorbital lobotomy, the disconnection of white matter tracts in the frontal lobes was achieved by inserting a metallic tool called *lobotome* into the skull through the eye orbits and by moving this instrument back and forth. This procedure, called *lobotomy*, was often performed in the 1940s and 1950s to treat refractory psychiatric illnesses. Almost invariably, lobotomy resulted in a significant neurological damage and was accompanied by neurological sequelae and personality alterations. Cingulotomy is another type of neurosurgery that has been used to treat severe obsessive compulsive disorder (OCD). This procedure disconnects the cingulate cortex from prefrontal regions. As it disrupts the brain pathways that convey the emotional and affective experience associated to nociceptive stimulation, cingulotomy has been used to alleviate intractable pain. A significant improvement has been observed in around 30% of patients treated with this procedure (see, for example, data collected in 30 years of medical praxis at the Massachusetts General Hospital, Dougherty et al., 2002).

Psychosurgery is in use nowadays for the treatment of symptoms associated to severe and refractory depression and OCD, which are not responsive to other medical interventions. Modern interventions rely on MRI-guided stereotactic procedures, which greatly increase surgical precision. The ability to specifically target selective brain regions can significantly increase effectiveness of neurological and psychiatric treatments. The risk of side effects always needs to be taken into account and evaluations of the ratio cost/benefits have to be carried out carefully for each individual. Nevertheless, relieving psychiatric symptoms may greatly increase subjective well-being and individual social integration, especially when those symptoms are particularly detrimental for daily life routines, as in the case of massive obsessive compulsions. Psychosurgery, by directly altering the functioning of neuronal substrates of psychiatric and neurological disorders, may be used as an effective treatment. Nevertheless, such invasive procedures may result in significant loss of cognitive functions and major personality changes. Thus, the application of these methods is not uncontroversial from the ethical point of view, as they may completely alter the sense of the self of the patient, leading to permanent changes in personal identity. This raises the question whether the effects of psychosurgery in these cases may not be worse than the illness itself.

Neurostimulation

Contrary to more invasive means of brain interventions, neurostimulation does not result in permanent brain lesions. Neurostimulation is usually performed by using microelectrodes that are implanted deeply in the brain, such as in subcortical structures. This technique is also known as *deep-brain stimulation* (DBS) and works by releasing electrical current directly in targeted brain regions, whose activity is altered in a number of neurological disorders. DBS has been employed successfully in the treatment of Parkinson's disease to allow patients to recover lost movement abilities. DBS has been shown to be particularly useful for patients with intractable tremor and with complications due to long-term treatment with levodopa (Volkmann, 2004). DBS has been used to inhibit hyperactivity within (*see* Epilepsy) epileptic foci in the treatment of drug-resistant epileptic patients. Also, severe depression has been shown to be responsive to this method of intervention (Mayberg et al., 2005). Finally, DBS is a promising technique for the treatment of refractory OCD (Lakhan and Callaway, 2010).

Importantly, DBS allows patients to actively control the level of stimulation that they receive by switching electrodes on and off. Reports of improper use of brain implants in patients with Parkinson's disease, including for erotic self-stimulation, have been described (e.g., Morgan et al., 2006). Abuse of stimulation with brain implants may also lead to compulsive gambling and financial problems in these patients.

The implanted electrodes are removable. Nevertheless, implanting electrodes carries the risk of lesioning brain areas that are adjacent to the targeted ones. Achieving a high precision in brain spatial placement is crucial in order to obtain the desirable therapeutic effects.

Potential neurological sequelae of DBS may vary according to the functions of the brain areas where implants are located and must be taken into careful consideration prior to each intervention. Also, stimulation of the intended brain portion may result in unforeseen side effects that may be due to alterations in its activity as well as to changes in activity of brain sites that are functionally connected to it.

Cognitive Enhancement

In human history, various types of substances including caffeine, nicotine, and cocaine have been used to enhance cognitive performances and reduce fatigue. In recent years, there has been a growing interest in the potentiation of attention and other cognitive functions. Cognitive enhancement can be achieved through the administration of different pharmaceutical products now available in the market. Both methylphenidate (Ritalin) and modafinil (Provigil) are examples of cognitive enhancers that are widely used to treat disorders of attention and vigilance. Modafinil was first introduced for treating narcolepsy and it can be employed for curing the shift-work sleep disorder and problems related to apnea during sleep. Modafinil is effective in the regulation of the sleep–wake cycle and circadian rhythms and greatly alleviates daytime sleepiness and reduces the rate of accidents in time-shift working people. As a performance enhancer, this drug has been used to increase alertness in healthy volunteers with no dysregulation of circadian rhythms who need to maintain a sharp cognitive functioning for prolonged periods of time. Cognitive functions that show an improvement as an effect of modafinil intake include pattern recognition and a reduction in reaction times (Scholey et al., 2012). The use of

drugs such as modafinil has many potential applications outside of those strictly clinical. For instance, modafinil may allow military soldiers to manage highly stressful and demanding tasks without losing concentration or facilitate the work of medical services that are active in high-risk emergency situations. Modafinil seems to selectively target the functioning of the hypothalamus (*see* Hypothalamus) in the regulation of the wake–sleep cycle. No addictive effects have been associated to modafinil so far. Nevertheless, (*see* Sleep and Memory) sleep plays an important role in crucial cognitive functions, such as consolidation of memory (*see* Learning and Memory, Neural Basis of) traces and synaptic (*see* Synaptic Mechanisms and Protein Synthesis in Learning, Memory, and forgetting) homeostasis. Sleep deprivation may lead to a higher incidence of hypertension and thus affect health in ways that may be unforeseen on a short time-period window.

Herbal extracts, such as from Guaraná, Sage, Ginseng, and Bacopa, are also widely employed for their effects as cognitive enhancers. In healthy young adults, for example, intake of Panax Ginseng has been shown to improve memory performances and reduce fatigue associated with prolonged cognitive effort (Scholey et al., 2012). Energy drinks that contain caffeine are also included in this category and are being popularly used especially by young individuals.

Inhibiting sleep or increasing the capacity to maintain alertness for prolonged periods of time by using pharmacological means may not come without negative side effects for health. Is it ethically acceptable to do so? Is it safe to use cognitive enhancers even though the biochemical mechanisms of their functioning on the central nervous system are still largely unclear? Epidemiological longitudinal studies should be carried out to gain a closer understanding of the short- and long-term effects of cognitive enhancers, both investigating positive and adverse side effects on health. Public institutions should implement informative campaigns that target the medical sector, schools, and families in order to give hints on adverse effects that these artificial aids may carry for health.

Finally, leaving aside medical considerations, it is important to keep in mind that social consequences are likely to be associated with the use of performance enhancers. The recourse to neuroenhancers is stimulated by contemporary cultural phenomena, including the strong competitiveness and the need to maximize immediate productivity and efficiency that are often seen in working environments. In theory, if the use of cognitive enhancers becomes too generalized, then everybody will need to assume them merely to achieve equal performances. Furthermore, cognitive enhancers may be available primarily to those who possess greater economic resources, thus contributing to increased social inequity. Finally, in high-risk jobs, the inability to maintain high performances for longer times without potentiation may expose to greater risks when enhancers cannot be used and the same performances cannot be achieved. Thus, many are the issues that should be taken into consideration as far as the use of cognitive enhancers is concerned. Among them, it is important to mention the value of equal opportunities, merit due to effort and hard work as well as fairness in society.

Brain–Computer Interfaces and Neuroprosthesis

Since the 1960s, researchers have investigated the effects of EEG (*see* Electroencephalography: Basic Principles and Applications)–biofeedback–trainings on behavioral performances. Clinical applications include the treatment of the attention deficit/hyperactivity disorder, the suppression of epileptic seizures, and the restoration of communication abilities in locked-in patients. More recent applications have shown the feasibility of near-infrared spectroscopy, (*see* Near-Infrared Spectroscopy) functional magnetic resonance imaging (fMRI), and magnetoencephalography (MEG)-based brain–computer interfaces (BCIs) to enable individuals to gain volitional control over circumscribed brain areas. Compared to the EEG counterpart, neurofeedback based on these methods provide real-time information on brain activity levels with high spatial resolution. As such, it can be used to study behavioral effects of activity modulation in areas of interest (e.g., Rota et al., 2009).

BCIs may rely on signals that are derived from brain activity as inputs to control electrical external devices. Clinical applications include rehabilitation and restoration of movement in patients with stroke and brain damages (*see* Brain Damage: Neuropsychological Rehabilitation) (see Birbaumer et al., 2008 for a review). Invasive BCIs rely on implanted brain electrodes and have been mostly investigated in animal models. Neuroprostheses (*see* Neuroprosthetics) allow animals to perform movements, as well as to reach and grasp objects by self-eliciting variations in brain activity.

The development of more and more sophisticated neuroprostheses raises several concerns about their potential misuse. Do the benefits of neuroprostheses and artificial body implants justify the risk of adverse health effects due to invasive surgical procedures? Is it desirable to achieve a permanent enhancement of human physical and cognitive capabilities with these methods? Will cyborgs and human/machine hybrids remain obscure characters of science fiction scenarios or is there a true potential for abuse?

Privacy Rights and Informed Consent

In recent years, attention has increased for the respect of personal autonomy and privacy rights (Beauchamp and Childress, 2009) of patients and healthy volunteers who participate in research studies. Each developed country has created a corpus of laws for the protection of privacy rights. In clinical trials and scientific studies, patients and healthy volunteers are required to receive all information concerning the procedures that they will undergo and the risks involved and to read and sign an informed consent. The ability to give an informed consent is grounded on the capacity to make a decision, which in turn relies on a number of cognitive functions such as attention, working memory, understanding, and general reasoning. The ability of the researcher to take the perspective of the consenting individual and to recognize his/her current emotional states is crucial for understanding whether he/she is able and willing to give an informed consent. Capability to give full consent to participation to a study is a particularly sensitive issue when it comes to patients with neurodegenerative disorders, *in primis* dementia, that affect cognitive abilities, or with mood disorders, that may impair

judgment and will. Given the importance of properly assessing decisional capacity for obtaining an informed consent, in recent years a number of clinical tests have been devised.

The Neuroscience of Ethics

In the 1990s, the so called *Decade of the Brain*, an amazing technological advancement in the investigation of the *in vivo* functioning of the human brain took place. Novel neuroimaging methodologies have made it possible to map complex cognitive and emotional processes (*see* Emotion, Neural Basis of) in the brain, thus paving the way to the study of the neural and molecular underpinnings that sustain the complexity of human behavior (Pietrini, 2003). The main neuroimaging technologies include positron emission tomography, single photon emission computed tomography, MEG, MRI, and fMRI. Neuroimaging can be employed to uncover the neuronal correlates of brain function both under healthy and pathological conditions. Also, direct information on the functioning of neural substrates of mental activity may provide psychiatrists with a direct feedback on the therapy's effectiveness allowing them to adjust their intervention accordingly and to prevent relapses, thus greatly improving subjective well-being.

Advancements in the methods of investigation and visualization of brain activity allow researchers to identify the neuronal underpinnings of morality and free-will. Also, molecular biology is shedding novel light on the genetic factors that modulate behavior, including control of impulses and expression of aggression. In the following sections, we briefly review the findings concerning moral judgment and free-will.

Moral Judgment

Moral evaluations (*see* Neural Foundation of Morality) are a crucial component of decision-making processes and are typically engaged when choosing among two or more competing options that may advantage ourselves or a third party. Imaging studies have relied on ethical dilemmas to study the neural underpinning of moral evaluations. Moral dilemmas typically consist of short stories that present a conflict of choices and the question as to whether a given action may be morally acceptable in a given situation. This paradigm relies on script-driven mental imagery, and it is typically applied for addressing complex emotional and cognitive processes that otherwise would be impossible to investigate in a scientific manner (see, for instance, the investigation of the neural correlates of forgiveness by Ricciardi et al., 2013).

Reasons and emotions are core elements for moral judgments. Plato was the first prominent thinker who described the dichotomy of reason and emotion in humans and advocated the role of reason in governing passions and guiding righteous actions. However, reason does not alone determine our moral choices. Evidence from neuroimaging studies shows that a strong interplay of reason and emotion takes place when people judge the acceptability of controversial moral choices (Greene et al., 2001). The trolley and the footbridge dilemmas are illustrative of the moral impasse created in such situations. In the first dilemma, subjects imagine viewing a runaway trolley on which the conductor lost control that threatens to kill five workers along the runaway if no action is taken. The only way for the subjects to save the five workers is to pull a lever that will divert the trolley onto an alternative set of tracks on which there is only one worker. This man will die, but the other five will be spared. In the footbridge dilemma, subjects have to imagine being on a bridge that overlooks the tracks and seeing the runaway trolley directing toward the five men. The only means they have to stop the trolley is by pushing a stranger next to them off the bridge onto the tracks, using his body to interrupt the trolley's run. Both dilemmas confront people with the same utilitarian reasoning: deciding to sacrifice one life to save five others. However, most people who engage in those judgments accept one person's death in the trolley but not in the footbridge dilemma. Greene et al. (2001) showed that the judgment of moral acceptability in the trolley dilemma is sustained by activation in brain areas (i.e., the dorsolateral prefrontal cortex (*see* Cerebral Cortex)) involved in utilitarian reasoning only (i.e., based on a cost/benefits calculation). On the contrary, when evaluating the footbridge dilemma, a conflict between reason and emotion arises and areas of the brain that are involved in emotional processing (i.e., the ventromedial prefrontal cortex) strongly become activated. This result suggests that emotion and rationality are intertwined aspects of moral decision making and that their role may become more or less relevant if the context in which the same moral question is framed changes. A number of factors have been shown to affect emotional involvement and brain responses in moral judgment, including the level of personalness and/or directness of the harmful action (e.g., whether there is spatial proximity between the agent and the victim and whether muscular force and direct contact are used by the agent, as, for instance, by pushing the victim off the bridge, or by activating a mechanical device that mediates the action, Greene et al., 2004, 2001).

Research in neuroethics allows for bridging deficits in emotions and empathy (*see* Empathy: A Social Neuroscience Perspective) with deficits in moral reasoning that may lead to impairments in moral judgment. In the antisocial personality disorder, (*see* Psychopathy) both emotional life and empathy are impaired (Pietrini and Bambini, 2009). Morphological alterations of brain structures crucial for moral judgments and impulse control, such as the medial prefrontal cortex (MPFC) and the dorsolateral prefrontal cortex, have been documented in psychopathic subjects who committed violent crimes (Boccardi et al., 2011). Consistently, Koenigs et al. (2007) have found that patients with damage in the ventral portion of MPFC engaging in moral evaluations highly prefer utilitarian choices, that is, choices that permit the achievement of a greater good even though they may be harmful to others.

Social categorization and stereotype also affect moral evaluations. The acceptability of causing harm to other people in order to achieve a greater good is influenced by their membership to the social group of the dilemma's judger (Cikara et al., 2010). Cikara and colleagues showed that individuals of extreme out-groups (e.g., homeless people) are more easily sacrificed for the survival of in-group members. This study specifically tested the Stereotype Content Model according to which our emotional reactions are affected by the levels of warmth and competence that we perceive in the

other. For example, elderly and children belong to high-warmth and low-competence categories, whereas police officers belong to a high-competence and high-warmth category. Social categories with high warmth are likely to elicit feelings of benevolence and prosocial behavior whereas low-warmth categories are more likely to elicit negative emotions, such as disgust. A prefrontal network linked to the resolution of complex tradeoffs that comprises medial, dorsolateral, and orbitofrontal regions is activated when volunteers decide to sacrifice low-warmth, low-competence targets to save in-group members. Thus, intergroup biases heavily affect neural reactivity during moral choices.

Intentionality in causing harm to others affects acceptability of the action itself. A great body of literature demonstrated a higher acceptability of harm that is the consequence of good intention, that happens accidentally, or that is the consequence of inaction (see Christensen and Gomila, 2012 for a review).

Ecological validity of experimental stimuli that are used for eliciting moral evaluations is an important condition that should be carefully taken into consideration while planning experimental tasks. Obviously, imagining scenarios in which soldiers combat is described as an easier and a more realistic task by individuals who had first-hand or vicarious experiences related to those scenes.

Finally, certainty of events is an important variable that so far has been barely controlled for. While full certainty about the future course of real-life events is rare, events depicted in moral dilemmas are usually presented in a way that they are bound to follow a certain course with no uncertainty. While this condition is due to experimental purposes, it may also represent a limitation to the ecological validity of the results.

Neurobiological Correlates of Free-Will and Potential Forensic Implications

Free-will has been the center of philosophical disputes over centuries and it is broadly understood as the ability to freely choose to engage in a given action over other ones that are available. Great interest for this topic has been stirred by the findings of Libet et al. (1983). The researchers investigated neuronal responses and subjective reports of individuals who freely performed motor acts, (*see* Cortical Areas Engaged in Movement: Neuroimaging Methods) showing that cerebral activity is detectable in the supplementary motor area (*see* Motor Cortex) a few hundred milliseconds before experiencing the subjective intention to move. Soon et al. (2008) used an fMRI motor-decision paradigm to show that activity in the prefrontal and parietal cortex is measurable up to 10 s before subjects become aware of their motor intention. Taken together, these findings suggest that unconscious brain activity influences an individual's volitional act long before it enters awareness. This argument has been used by some to challenge free-will (e.g., Wegner, 2002). For others, these data merely suggest that the conscious experience of an intention needs a longer time to build up (see Guggisberg and Mottaz, 2013 for a review).

Free-will also implies the ability to exercise volitional will-power on one's own choices. As such, free-will may not be properly conceptualized as a binary 'on–off' variable. It may rather consist of a scalar variable that comes in degrees. Thus, individuals on one side of the spectrum are completely deprived of volitional control on their behavior and of criminal responsibility for their acts. On the other side, individuals fully possess the ability to inhibit impulsive behavior, especially in situations where they are exposed to social triggers that may lead others to aggressiveness and violence.

A number of applications of neuroscientific methods in forensic settings, such as for lie and memory detection, have stirred great interest in the scientific community (e.g., Sartori et al., 2011). The use of diagnostic brain imaging methods may have important implications in court as these exams may provide information regarding anatomical alterations that may compromise the functioning of brain areas that are crucial for the control and inhibition of impulsive behavior (Pietrini and Bambini, 2009). Scientific evidence has linked lesions and hypofunctionality of the prefrontal cortex to impulsive, violent, and antisocial behavior (e.g., Pardini et al., 2011). These data have also been supported by consistent findings in healthy controls with no history of violence (Pietrini et al., 2000). Reduced gray matter in prefrontal regions and increased activation in the amygdala, a region that controls emotional reactivity, have also been documented in violent and antisocial behavior (Raine et al., 2000; Davidson et al., 2000).

Behavioral genetics has expanded our understanding of genetic influences on antisocial behavior. For instance, previous research has linked some alleles of a few genes as MAOA, 5-HTTLPR, COMT, and DRD4 to aggressiveness and violent behavior (see Iofrida et al., 2014 for a review).

Specific genetic variants have been associated to variations in functionality and morphology in brain areas critical for the inhibition of aggressive impulses. Are these findings moving us toward a *molecular* ethics (Pietrini, 2003)? What are the consequences of this evidence for the notion of free-will?

A recent sentence in Italy has stirred great international interest as neuroscientific evidence, including brain imaging and genetic evaluations, was used in court to account for a reduced ability of the defendant to control impulsive behavior. In this case, the presence of genetic variants linked to violent behavior and neuroimaging evidence of poor control of impulsive behavior led the judge to shorten the sentence of jail for the offender (Pellegrini and Pietrini, 2010). In the future, evaluations of criminal responsibility may be greatly facilitated by a deeper understanding of the neural signatures on normal and abnormal behavior. Importantly, neuroscientific and behavioral genetic investigations may greatly improve psychiatric assessment by providing objective data on the neuronal bases of a criminal's mental disorder (Rigoni et al., 2010; Sartori et al., 2011). This is very relevant as it may lead to the development of interventions for rehabilitation that will be tailored to each individual's capacities and potentials.

Conclusions

From its first introduction in 1973 the word *neuroethics* has come to indicate on one hand the ethical issues that arise in many fields of neuroscience research and their clinical applications and on the other the neurobiological bases of ethical functions. Innovative structural and functional brain imaging methodologies have made it possible to enter the era of a fascinating journey through the human brain in search of the

mind, so that ancient philosophical questions can now be approached from a neuroscientific perspective. The results of these studies are shedding new light on our understanding of brain functions, including moral judgment and decision-making processes, with implications that fall far beyond the mere field of neuroscience, as they affect ethics, philosophy, and even the law itself. At the same time, the development of more and more sophisticated tools is leading to unprecedented opportunities to treat brain disorders or restore lost functions through the use of neuroprostheses and brain implants. As neuroscience is advancing with no pause, neuroethics will witness greater and greater challenges in the years to come.

Neurolinguistic Processing of Psychological Verbs

Jonathan Brennan, The University of Michigan, Ann Arbor, MI, USA

Abstract

Psychological verbs are used to communicate how we feel by describing mental states such as 'love,' 'amuse,' and 'bother.' These verbs denote a particular class of concepts and have been found across many languages to have unique syntactic and semantic properties that offer a window in to how meaning is grammatically encoded. Aphasiology, electrophysiology, and neuroimaging studies have leveraged the unique conceptual and grammatical properties of these verbs to shed light on neural mechanisms involved in representing concepts, identifying argument roles, and building complex compositional meanings. A recurring theme across this diverse field is the challenge of linking the representational properties of these verbs, which remain debated in linguistics, with specific neurobiological mechanisms.

Introduction

Language is commonly used to communicate how we feel. Verbs such as 'love,' 'appreciate,' 'amuse,' and 'bother' convey the mental, or psychological, state of the participants in a sentence (see Levin, 1993: 188–192 for a comprehensive list). 'Psych verbs,' or PVs, contrast with verbs that describe actions, activities, and other things that individuals *do*. This difference is one of lexical/conceptual semantics, or word meaning. Neuroscientists have used the unique semantics of this class of verbs to gain insight into how the brain represents abstract concepts like that denoted by the word 'love.' Linguistic research has also found that PVs have numerous interesting syntactic and compositional semantic properties. Thus, PVs also offer a window in to how the meaning of a sentence relates to its syntactic structure and accordingly provide insight into the neural mechanisms that underlie grammar. The sections below discuss the relevant linguistic properties of PVs and then provide a comprehensive review of the cognitive neuroscience research that has used these verbs.

Linguistic Properties of Psychological Verbs

Also called 'experiencer verbs' or 'mental verbs,' PVs have numerous lexical, syntactic, and compositional semantic properties that set them apart from other verbs (Belletti and Rizzi, 1988; Grimshaw, 1990; Baker, 1997; Pesetsky, 1995; Landau, 2009). This section reviews three key properties most important for neurolinguistic research in this area: (1) the grammatical argument structures specific to these verbs, (2) their compositional semantics, and (3) their lexical semantic properties.

Most discussed in the linguistic literature is the syntactic argument structure of PVs. Whereas most transitive verbs associate the subject of a sentence with the 'doer' or thematic agent of the action described by the verb, as in the example sentences in (1), PVs vary as to whether the thematic role of the subject is the 'experiencer' of the mental state denoted by the verb, or whether it is the object of the sentence that experiences the mental state. The sentences in (2) illustrate so-called 'subject experiencers' (SE) while those in (3) illustrate 'object experiencers' (OE).

1. a. Mary kissed John.
   b. Mary drove a truck.
2. a. Mary adored John.
   b. Mary distrusted John.
3. a. Mary amused John.
   b. Mary frightened John.

The thematic variation found in psychological verbs contrasts with other classes. For example, no English verbs encode the agent role in the object position. This fact is one of many that suggests there are grammatical restrictions on how thematic roles are syntactically encoded (Baker, 1997).

There is significant debate over the sorts of mental representations necessary to capture PV argument structure. One view holds that both SEs and OEs share a common syntactic core in which the 'experiencer' is always the subject, but for OE verbs, an additional layer of syntactic structure is necessary which leads to the observed word order (Belletti and Rizzi, 1988; Grimshaw, 1990). The word ordering comes about because the nonexperiencer argument of the verb has 'moved' to the syntactic position of the sentential subject to form a long-distance dependency. To get an intuition of this kind of theory, consider sentences such as *the boat sank* compared with *the torpedo sank the boat*, and observe that the subject of the first sentence has the same thematic role as the object in the second. To say that 'the boat' moves from the object to subject position in the first sentence captures the fact that this noun phrase has properties of both a subject and (thematic) object (e.g., Burzio, 1986). Others, noting nuanced semantic differences between OE and SE verbs, contend that OE verbs contain a more complex verb phrase which denotes a complex multi-part event (Pesetsky, 1995). This can be seen by contrasting the thematic role played by 'news' in the two sentences in (4a, b). While (4a) is well-paraphrased by saying that the news 'caused' John to be angry, even if the anger is not directed at the news (e.g., there was a political event that John did not like), in (4b) the object of anger must be the show itself (e.g., the format of the show was upsetting). Further, it is infelicitous to deny a causal connection for OE verbs (4c), but in contrast, it is easy (if stylistically awkward) to do so for SE verbs (4d). The causal meaning in (4a) is argued to require more complex verb phrase syntax, attributed either to a multilayered verb phrase

 http://dx.doi.org/10.1016/B978-0-08-097086-8.54044-6

(Pesetsky, 1995; Pylkkänen, 2000) or a more refined verbal ontology (Arad, 1998).

4. a. The news show angered John.
   b. John was angry at the news show.
   c. # The news show angered John thought it did not make him angry.
   d. John trusted the news, though the news did not make him trust it.

To summarize, some theories attribute syntactic differences to syntactic movement (Belletti and Rizzi, 1988; Grimshaw, 1990), others to complex verbal structure (Pesetsky, 1995; Pylkkänen, 2000) or a different verbal ontology (Arad, 1998), while still others remain agnostic as to whether there is a difference in syntactic complexity (Dowty, 1991; Baker, 1997). Thus, while many (though not all) linguistic accounts take OEs to be more complex syntactically than SEs, the source of that complexity remains debated.

Independent of these syntactic debates, there is general agreement that there are semantic differences between these verb classes which may (Pesetsky, 1995) or may not (Baker, 1997) have syntactic consequences. These two kinds of PVs are distinguished both by the kinds of events that they denote and by the complexity of their entailments (Brennan and Pylkkänen, 2010), a domain of grammar called 'aspect.' The present discussion will focus on the difference between state-denoting phrases, such as 'be asleep,' 'is tall,' or 'loves tomatoes,' and non-states such as 'walk around the lake,' 'arrive at the store,' or 'build a house,' setting aside numerous finer distinctions. The term 'eventualities' will be used to describe both states and non-states, while the latter alone will be labeled 'events' (Bach, 1986).

States can be distinguished from events in English based on how they behave in the present tense. Present tense eventive verb phrases carry a habitual meaning, as shown in (5), such that the event need not be occurring at the time of utterance (Dowty, 1979). In contrast, stative verbs lack an habitual interpretation in the present tense, rather the denoted eventuality must hold at the time of utterance (6). (The hash mark '#' indicates sentences with a pragmatically odd or infelicitous meaning.) The interjective 'Look!' provides further evidence for this distinction as it forces a nonhabitual interpretation and thus is only appropriate when the eventuality holds at the time of utterance (7) (Brennan and Pylkkänen, 2010). According to these diagnostics, the sentences containing SE verbs in (8) and (9) lack a habitual implication, and thus pattern like the state-denoting predicates in (6) and (7b) and unlike the event-denoting predicates in (5) and (7a).

5. Mary runs in the park, though she is not running at the moment.
6. # Mary is asleep, though she is not asleep right now.
7. a. # Look! Mary runs in the park.
   b. Look! Mary is asleep.
8. a. Look! The child trusts the teacher.
   b. Look! The baby likes the toy.
9. a. # The children trust the teacher, though they do not at the moment.
   b. # The baby likes the kitty, though she does not like it today.

These diagnostics show that SEs are stative. The aspectual properties of OEs are more complex; essentially, they sometimes pattern as state-denoting, and sometimes as event-denoting predicates. For example, the sentences in (10) show that OE verbs are interpreted habitually in the present tense and, accordingly, need not entail that the mental state holds at the time of utterance.

10. a. The students amuse the coach, but she is not amused right now.
    b. Those horses frighten the dog, but he is not frightened right now.

In this way, OEs differ from SEs (compare the sentences in (10) with those in (9)). However OEs appear to be stative in other contexts, as can be seen with the 'Look!' test (11).

11. a. Look! The students amuse the coach.
    b. Look! Those horses frighten the dog.

It appears, then, that OEs can be interpreted as states or as events as dictated by the context, a flexibility in aspectual interpretation dubbed 'coercion' (Moens and Steedman, 1988). Note, however, that the event denotation of SE verbs is not entirely inflexible. The sentence in (12) demonstrates that SE verb meanings may also be coerced in certain limited circumstances.

12. Within 10 minutes, the children trusted the teacher.

This sentence is interpreted to mean that the children have begun to trust the teacher by the end of the time interval described. When combined with a durative modifier, SE sentences denote a change of state event, rather than a simple state.

SE and OE verbs also differ in the complexity of their entailments (Pesetsky, 1995): whereas OEs with living subjects entail that the subject *caused* the mental state to hold of the experiencer in object position, SEs contain no such entailment. Note that the presence of this entailment should be considered separately from whether it affects the syntactic argument structure of these sentences (see the discussion surrounding example (4) above). The sentences in (4) above illustrate the causative entailment of OEs. Importantly, it is infelicitous to explicitly reject a causal connection for OE verbs (4c) but not for SE verbs (4d). The absence of causal semantics in SEs is what permits, considering the example sentence in (4d), the absence of causal semantics in SEs an interpretation by which 'John' can trust the news even if the news show has never done anything to earn that trust (perhaps John is a trusting person).

To summarize, OE and SE psychological verbs differ in at least three relevant respects: (1) OEs contrast with SEs in having a noncanonical argument structure that arguably involves a more complex syntactic structure (2) OEs more flexibly denote different kinds of eventualities than SEs, and (3) OEs have more complex entailments than SEs. All of these properties will bear on the extant neuroimaging findings.

Finally, of course, by definition PVs differ from other classes of verbs in the concepts they denote. By denoting mental states, not observable actions or events, PVs serve as a window into so-called 'embodied' theories of concepts: to what degree are concepts for words represented in terms of perceptual and

motor-based neural systems. PVs lack concrete visual, auditory, or other sensory properties and are also not strongly associated with canonical motor actions or movements. Thus, they offer a class of linguistic stimulus to compare with verbs that do have concrete perceptual or motoric associations.

Neurolinguistic Research Using Psychological Verbs

This section divides neurolinguistic research using psychological verbs into three domains based on the types of questions being asked. One body of literature, drawing on aphasia studies, electrophysiology and neuroimaging, has investigated brain mechanisms involved in identifying thematic roles and verbal argument structure using PVs. A second literature has probed compositional semantic processing with PVs. Lastly are studies using patient populations and neuroimaging that have focused on conceptual representations.

PVs and Argument Structure

The syntactic properties of PVs have been leveraged in the study of the language disorder of agrammatical aphasia. There has been debate over how best to characterize the grammatical deficit(s) that underlie this disorder (see e.g., Grodzinsky, 2001 and associated commentaries). One hypothesis points to difficulties representing long-distance dependencies, such as the relationship between the subject and the verb in a passive sentence such as *The truck was driven by Mary*. See the discussion on p. 1. If such a dependency cannot be represented by the patient then they cannot recover the proper thematic role, raising the question of if and how any thematic roles are interpreted.

Grodzinsky (1995) argues that passive SE sentences provide a test for whether patients with agrammaticism use nonsyntactic heuristics. In (13) *t* indicates the grammatical object position which forms a long distance dependency with the subject in passive sentences. (The discussion here elides the additional dependencies required by the verb-internal subject hypothesis (Sportiche, 1988).) Failing to represent dependencies, Grodzinsky argues, these patients employ a heuristic which assigns the agent role to the first noun phrase. Considering the example in (13), an 'agent-first' heuristic will grant the agent role to 'the man' and a theme role to 'the woman.' Thus, the sentence will be interpreted as an active sentence with thematic reversal (e.g., the man will be doing the desiring, opposite the intended meaning). Consequently, agrammatic aphasics should show below-chance performance on passive SE sentences in comparison to active SE sentences and non-PV controls.

13. (The man)$_{THEME}$ was desired *t* by (the woman)$_{EXPERIENCER}$.

Grodzinsky (1995) reports results from a sentence–picture matching task in which four agrammatic patients with left frontal, frontotemporal, and/or frontoparietal damage that are in accordance with these predictions. These results appear to support the use of the 'agent-first' comprehension heuristic in this patient population.

Beretta and Campbell (2001) argue against this conclusion by comparing comprehension of OE and SE verbs in active and passive sentences with two agrammatic patients. They observe chance, not below-chance, performance for SE passives and report above chance performance on all other conditions. They take the contrast between chance performance on SE verbs and higher performance on passive OE verbs to reflect syntactic differences between these verb classes Following (Belletti and Rizzi, 1988), Beretta and Campbell assume that OE verbs form so-called 'adjectival passives' which contain fewer long-distance dependencies than passive sentences with SE verbs (but cf Pesetsky, 1995: chapter 2); these constructions are thus less affected by a deficit specific to long-distance dependencies. Beretta and Campbell reconcile the differences with Grodzinsky's findings by noting that the patients in the earlier study had relatively extended lesions and that certain PVs might have been difficult to visualize for the picture–sentence matching task (e.g., 'understand', 'trust'), thus inflating task difficulty.

The same pattern of comprehension results is reported by Thompson and Lee (2009) in a study of eight agrammatic patients with left hemisphere lesions. Thompson and Lee also conducted an elicitation study with comparable results, and find that OE verbs showed more errors in the active compared to passive voice. They attribute the degraded active voice performance to either increased syntactic complexity (Belletti and Rizzi, 1988) or added semantic complexity (Pesetsky, 1995) in these verbs.

The results from Beretta and Campbell and Thompson and Lee appear to argue against the operation of a nonlinguistic 'agent-first' heuristic. However, to explain the increased performance for OE passives compared to actives, Thompson and Lee, following Ferreira (1994), appeal to an alternative heuristic which prefers for arguments with prominent thematic roles to precede those with less prominent roles (in accordance with a 'thematic hierarchy' e.g., Jackendoff, 1987). Thus, passive OEs would be more frequently produced by agrammatic patients because the higher-ranked experiencer occurs first and the lower-ranked theme argument argues second.

These two findings need reconciliation: (1) chance performance for SE passives but not SE actives and (2) increased performance for OE passives compared to OE actives; while (1) precludes a strong 'agent-first' heuristic, (2) calls for some sort of heuristic which prefers for experiencers to precede themes. Note that this pattern cannot reflect syntactic differences between OE and SE passives as such differences would predict equal performance for OE passives and actives. One possible reconciliation retains weak heuristic that biases towards the inclusion of an agent role, but holds that agent and experiencer roles are not ordered with respect to each other. A lack of ordering may be plausible given that these roles never occur within the same clause in English. Under this view passive SE sentences like that in (13), when comprehended by agrammatic aphasics, contain two unordered roles neither of which is linked to a noun phrase, thereby leading to observed chance performance.

Argument ordering heuristics have also been argued to play a role in syntactic parsing in unimpaired populations. Researchers have suggested that sentences with noncanonical orderings (like OE verbs) might require additional argument structure processing, and therefore might shed light on the neural mechanisms involved in determining such structure. Electrophysiology and neuroimaging research that has pursued this aim is discussed next.

Bornkessel and colleagues have leveraged the unique properties of PVs in a series of experiments using event-related potentials (ERPs) and functional magnetic resonance imaging (fMRI) (Bornkessel et al., 2003, 2005). In verb-final German clauses, a parsing heuristic that assigned thematic roles relying simply on word order would require revision upon encountering an OE verb with reversed thematic roles (the higher-ranked experiencer role occurs in the object position). Such a mismatch would increase processing costs. These experiments use two properties of German to examine what kinds of heuristics might influence thematic role assignment. German permits the arguments of a verb to be ordered freely with respect to each other in certain circumstances (a phenomenon called 'scrambling'). Further, definite noun phrases carry grammatical case, which mark each noun's grammatical role irrespective of word order. The key question is whether OE verbs elicit a systematic neural response when the verb is encountered that patterns with a mismatch between the the argument structure inferred from word order, and the structure required by the verb. Examples of the stimuli are given in (14) (Bornkessel et al., 2003: 279–280). In these examples, NOM stands for Nominative case, which indicates the subject of a sentence and typically has the more prominent thematic role; DAT stands for dative case which is used for the direct or indirect object and typically has a less prominent role.

14. a. Active (NOM-DAT)
    … dass der Priester dem Gärtner folgt und …
    … that the$_{NOM}$ priest the$_{DAT}$ gardener follows and …
    '… that the priest is following the gardener.'
    b. ObjExp (NOM-DAT)
    … dass der Priester dem Gärtner imponiert und …
    … that the$_{NOM}$ priest the$_{DAT}$ gardener impresses and …
    '… that the priest impresses the gardener.'
    c. Active (DAT-NOM)
    … dass dem Priester der Gärtner folgt und …
    … that the$_{DAT}$ priest the$_{NOM}$ gardener follows and …
    '… that the gardener is following the priest.'
    d. ObjExp (DAT-NOM)
    … dass dem Priester der Gärtner imponiert und …
    … that the$_{DAT}$ priest the$_{NOM}$ gardener impresses and …
    '… that the gardener impresses the priest.'

Using ERPs, Bornkessel et al. (2003) find an increased early (200–350 ms) positivity for DAT-NOM sentences at the presentation of the second noun. They take this to indicate syntactic reanalysis: the initial dative noun phrase led the reader to temporarily believe that the phrase was going to be in the passive voice. At the verb they report a later positive effect (300–600 ms) for OE verbs compared to Active controls, which they take to reflect a mismatch between the thematic roles assigned prior to encountering the verb and the argument structure of the OE verb. Noting that both positivities occur earlier than the familiar P600 component associated with standard syntactic reanalysis (Osterhout and Holcomb, 1992; Kutas et al., 2006), Bornkessel et al. suggest that the effect reflects a nonsyntactic 'thematic' reanalysis, and thus favors nonsyntactic heuristics in thematic role assignment. However, the results are equally compatible with a predictive syntactic parsing algorithm (e.g., Sedivy et al., 1999; Chambers et al., 2002) for which the most likely verbal structure is postulated based on the noun phrase arguments and case marking. Such predictions would allow the assignment of thematic roles, but necessitate reanalysis when an OE verb was encountered. This alternative view is compatible with early effects of syntactic reanalysis associated with the diagnosis, rather than the repair, of a mismatch (e.g., Friederici and Mecklinger, 1996) as well as the absence of any interaction with word order, which would have been predicted if a word-order based heuristic influenced thematic role assignment.

To identify the neural generators of these effects, Bornkessel et al. (2005) examine stimuli similar to those in (14) using fMRI. In contrast to the ERP results, they report a network of left hemisphere regions where activity showed an interaction between verb type and word order, including inferior frontal gyrus (LIFG), inferior frontal junction (LIFJ), ventral premotor cortex, posterior superior temporal sulcus (LPSTS), and the intraparietal sulcus (LIPS). While they relate the LIFJ and LIPS activation to task-specific demands, they distinguish two different activation patterns in the LIFG the LPSTS. In the LIFG, the interaction reflects an increase in activation for noncanonical (DAT-NOM) ordered sentences with Active verbs paired with the reverse pattern for OE verbs; that is, these regions showed increased activation whenever the thematic order of the arguments was mismatched to the preferred order of the verb. The LPSTS, on the other hand, while showing a similar pattern for Active verbs, showed no effect for experiencer verbs.

The mismatch between the interaction effects observed in this fMRI study and the two main effects, separated in time, seen in the ERP study challenge a simple interpretation of the-processes indexed by these activations. The limited time resolution of fMRI means that the interaction results reflect processing stages that occur over many seconds and the observed interaction may reflect a summation of preverbal word-order effects and verb-driven reanalysis effects. Bornkessel et al. offer an alternative perspective, suggesting that the LPSTS pattern reflects processes sensitive to the match between the result of a word order-based heuristic and the thematic structure of the verb, while LIFG pattern reflects linearization processes that are taxed most by noncanonical arguments with Active verbs, and less so by variable argument ordering in OEs. This interpretation is compatible with the aphasia results reviewed above where left fronto(temporal) damage correlated with declined performance with passive-voice SE and active-voice OE verbs, both of which conflict with a word order-based heuristic. Given, however, the mismatch between the fMRI patterns and the ERP results above, however, the precise interpretation of the underlying cognitive processes remains unclear.

The above discussion has focused on syntactic argument structure, yet the contrasting verb types used in these studies differ in more than the order of thematic roles. As discussed above, OEs also have distinct semantic characteristics including causativity and a capacity for coercion. While neither semantic property is unique to just these verbs, the studies under consideration do not provide the set of activity verbs used, leaving open the role semantic differences may play in the observed neural differences.

PVs and Compositional Semantics

The discussion of argument structure has reached limited conclusions in part because the relationship between syntactic argument analysis and semantic composition remains poorly understood. Two studies of thematic role violations with PVs illustrate the difficulty in addressing this issue. Bourguignon et al. (2012) contrast English SE sentences and agentive sentences (e.g., "the boys have eaten the cake") containing either animate or inanimate subject noun phrases, the latter of which are semantically implausible. For agentive verbs, animacy violations lead to the so-called 'semantic P600' (sP600) (e.g., Kim and Osterhout, 2005; Kuperberg, 2007). The sP600 has received significant attention because these animacy violations might have been expected to lead to an N400 associated with lexical semantic implausibility (Kutas and Hillyard, 1980; see Lau et al., 2008 for a review). Interestingly, inanimate subjects with SE verbs do, in fact, lead to an N400 followed by a P600, in contrast to inanimate subjects with agentive verbs. Furthermore, Paczynski and Kuperberg (2011) test OE verbs against control verbs that select for animate 'patient' objects (e.g., *the guards punished the convict*) and they find an N400–P600 effect for infelicitous inanimate objects for both verb types, and no interaction effect. In sum, animacy violations lead to an N400 effect for experiencer subjects, experiencer objects, and patient objects but lead to the sP600 for subjects.

This pattern is puzzling if the sP600 reflects a mismatch between semantic composition and non-syntactic thematic heuristics that are guided by noun-phrase animacy (Kuperberg, 2007): why would animacy affect interpretation differently in object versus subject position for agentive verbs but not PVs. A possible answer lies in how semantic composition is balanced with syntactic reanalysis during parsing. The semantic mismatch between animacy and subject experiencers is of a different kind than with inanimate agents: inanimate noun phrases often have quasi-agent roles (e.g., "the car hit the wall") but they cannot be granted mental states without a semantic shift, for instance by anthropomorphizing the noun's denotation. Perhaps this semantic difference licenses distinct repair mechanisms for the two types of animacy mismatches when they occur in subject position. When mismatch is in object position, in contrast, the parser may have committed more fully to the argument structure, restricting syntactic reanalysis and thus leading to the expected semantic mismatch for inanimate objects regardless of verb type. Further work testing animacy violations against other semantic mismatches may help tease out the relative weight compositional factors play in argument structure analysis.

Neural mechanisms involved in resolving semantic mismatches have been the subject of an independent line of research in which PVs have also played a role. As described above, OE and SE verbs differ semantically in at least two respects: OEs contain a causative entailment absent in SE verbs, and OEs can be more easily coerced to refer to different kinds of events. The former is a difference in lexical semantics, while the latter taps into compositional semantics. Brennan and Pylkkänen (2010) manipulated these two properties to explore the neural mechanisms behind these two distinct kinds of semantic processing in the brain.

By using PVs, Brennan and Pylkkänen sought to maximize the similarity between target expressions. They compared triplets such as those in (15). Comparing SE with OE verbs (15a vs 15c) allowed testing of the lexical semantic differences between these classes of verbs. For coercion, the durative adverbial modifier in (15b), but not the nontemporal modifier in (15a) in combination with a stative SE verb results in a coerced change of state interpretation (see the discussion of example (12)).

15. a. Without a doubt, the child cherished the precious kitten.
    b. Within a few minutes, the child cherished the precious kitten.
    c. Without a doubt, the child scared the precious kitten.

Earlier literature suggests that both types of complexity engender a behavioral processing cost (Gennari and Poeppel, 2003; McKoon and Macfarland, 2000; Frisson and Frazier, 2005; McElree et al., 2001; Traxler et al., 2002, 2005; Piñango et al., 1999, 2006; Brennan and Pylkkänen, 2008), though no studies have directly compared the two. Further, coercion has been linked with a specific neural signature in a series of magnetoencephalography (MEG) studies (see Pylkkänen et al., 2011 for a review): an increase in anterior neuromagnetic activity spanning the midline within 200–500 ms after encountering a word that requires coercion. With this background, the contrasts in (15) using PVs served to connect the otherwise independent prior studies of each type of semantic complexity.

Brennan and Pylkkänen examined these contrasts behaviorally, using a self-paced moving window reading protocol, as well as using MEG. In self-paced reading, both kinds of complexity, lexical semantic complexity (OE vs SE) and coercion (SE states vs SE changes of state), led to increased reading times at the word immediately following the verb (see also Cupples, 2002; Ferreira, 1994). Using MEG, Brennan and Pylkkänen found an increase in left anterior temporal and left ventromedial brain activity for coercion sentences compared to control sentences within 200–400 ms following verb presentation, but found no differences for lexical semantic complexity. These results support a neural distinction between mechanisms responsible for processing lexical semantic and those responsible for processing compositional semantic information engaged by coercion. Left open, though, is what neural resources are engaged by lexical semantic complexity.

A notable limitation of these results is that the lexical semantic manipulation may covary with possible syntactic differences between these two verb classes as well as by the difference in semantics that permit OE verbs to more flexibly denote different kinds of events. Both of these factors may play a role in explaining the behavioral slowdown, though the null MEG results for lexical semantics do not provide any data that bear on this collection of differences. This null result is, furthermore, somewhat surprising in the context of the aphasia and fMRI data reviewed above which showed effects in the left inferior frontal gyrus for OE compared to SE verbs. The different results may be due to temporal properties of the underlying processes. For example, extended or offline interpretive processing that differs between verbs may be

apparent in the fMRI data but not in the rapid MEG signal. The absence of an MEG effect should not be overinterpreted, however, as it may reflect reduced sensitivity of MEG to the relevant cortical signals, among other possibilities.

PVs and Conceptual Representation

The last domain for review addresses the neural bases of conceptual representation. A long-standing debate concerns the degree to which conceptual representation is embodied, or grounded necessarily in motor and/or perceptual systems (see Pulvermüller and Fadiga, 2010; Barsalou, 2008 for reviews). An important test of this hypothesis is whether the comprehension of verbs that are associated with concrete actions and/or with specific visual characteristics, such as high motion, requires motor and/or perceptual neural systems, or whether comprehension relies on amodal neural resources. In this large literature, PVs have recently emerged as an important class of control stimuli as mental states typically lack concrete motor and sensory associations. Only a few studies have used PVs for this purpose, but the findings have rather interestingly shown only limited neural differences between verbs that denote mental states and those with more concrete denotations. A note of caution is warranted as extant studies offer only minimal description of the class of words they count as PVs ('mental' or 'abstract' verbs) and do not exhaustively list their stimuli, thus the linguistic details of these stimuli are not well characterized. If, however, this pattern stands up to further scrutiny, it will have important consequences for theories of embodied conceptual representation.

Using fMRI, Tettamanti et al. (2005) examined the brain response to spoken sentences from four categories, those with verbs describing oral actions (e.g., 'bite'), hand actions ('grasp'), foot actions ('kick'), and so-called abstract verbs (the SE 'appreciate' is given as an example). Increased activity for the three 'action' conditions compared to the 'abstract' (PV) condition was observed in the left inferior frontal gyrus (pars opercularis). Comparing each action condition individually to the abstract condition revealed additional anterior inferior frontal (pars triangularis) activity for mouth sentences, left precentral and left inferior temporal gyri for hand sentences, and left dorsal premotor cortex for leg sentences. These patterns are suggestive of motor-related activity for hand- and leg-verbs, but not mouth-verbs. Further, they do not bear on whether such activation reflects processing necessary for comprehension, or whether it reflects associative activation (cf Hickok, 2013).

Kemmerer et al. (2013) test whether motor neural systems play a causal role in conceptual processing by compare the comprehension of action (running, hitting, cutting, and speaking verbs) and nonaction (change-of-state verbs and PVs) verbs by participants with and without Parkinson's Disease (PD). PD is a neurodegenerative disease involving disruptions to motor and premotor regions causing severe movement disorders. The strong embodiment hypothesis holds that impaired motor systems will negatively impact conceptual processing of verbs with motor-related semantic features, but not verbs that denote concepts without motor features. This hypothesis is not supported by their results, which show equal performance by patients with PD and neurotypical controls in a semantic matching task for action verbs and abstract verbs such as PVs.

Turning to perceptual embodiment, further evidence that PV and action verb representation relies on similar neural substrates comes from Bedny et al. (2008, 2012). These studies focus on the degree to which concepts that imply motion engage brain regions involved in motion perception. Using fMRI, Bedny et al. (2008) compare high-motion, medium-motion, and low-motion nouns and verbs; the low-motion verb class is comprised of PVs. Consistent with previous research, high-motion verbs compared to low-motion nouns engage a posterior region of the left temporal lobe that has been implicated in motion perception. To test whether this activation reflects motion processing per se, or more abstract grammatical processing, Bedny et al. compare low-motion verbs (PVs) with high-motion nouns (words denoting animals) and find that the target region shows greater activation for PVs, consistent with an account of this region based on grammatical class (i.e. verb vs noun) and in contrast an account based on motion perception. In the same vein, Bedny et al. (2012) used similar stimuli and compared processing between congenitally blind and sighted individuals. Examining the same posterior temporal area, the results replicate an effect of grammatical class (verb vs noun), and the absence of an effect for motion (e.g., high-motion nouns vs low-motion PVs). Furthermore, in both region-of-interest and whole-brain analyses they find no regions that differentiate high-motion action verbs from PVs, in contrast to Tettamanti et al.'s findings described above, nor did they find any activation that was sensitive to the motion contrast and differed between blind and sighted individuals. In other words, no activity differentiated high from low-motion verbs, and visual experience did not explain the activation patterns that distinguished high-motion nouns from low-motion psychological verbs.

These studies provide limited evidence for embodiment; the results are compatible with abstract amodal conceptual representations. Follow-up work should consider the fine-grained as well as coarse-grained lexical semantic differences between PVs and other verb classes. For instance, the causal meaning present in OEs could lead to activation not found in noncausal verbs (e.g., verbs of speaking) that could be mistaken for conceptual-related differences. Using SE verbs would address this one concern but introduce a possible confound between verb class and event aspect as states are less complex than activities (Gennari and Poeppel, 2003; Brennan and Pylkkänen, 2010). To serve as an ideal control stimulus, PVs must be contrasted with other verb classes that denote similar kinds of events, differing only in the degree to which the latter contain concrete perceptual and/or motor associations.

Conclusions and Future Directions

This article has focused on three areas of neurolinguistic research that have been studied using psychological verbs: argument structure processing, semantic complexity, and conceptual representation. While PVs have played a role in

several key debates, a theme throughout the article has been the challenge posed by correlations between lexical semantic, compositional semantic, and syntactic properties of these verbs. As such, extant findings cannot neatly tease out syntactic from semantic effects in terms of neural activity or behavioral patterns in patients.

This difficulty is amplified by the linguistic debates surrounding these predicates, in particular there is real disagreement over the syntactic representation of the OE subclass of PVs. Attempts to reconcile poorly understood linguistic representations with neural findings risk limiting progress as uncertainty in both domains may lead to ill-formed research questions (a progression labeled 'mutual sterilization' by Poeppel and Embick, 2005). To meet this challenge, studies must take in to account the full range of conceptual, semantic, and syntactic properties of PVs. To give one concrete example, research testing the mechanisms involved in reconciling noncanonical argument ordering by comparing SE with OE verbs might address the confound between argument ordering and the presence of causative meaning in OEs by including a control condition that contained causal meaning with otherwise canonical argument ordering, as found with causative verbs such as in *The torpedo sank the boat* or *The hot sun melted the ice-cream*. Identifying more granular comparisons that isolate specific representational properties of PVs will facilitate efforts to increase the precision with which neural mechanisms can be linked with linguistic processes.

Abstract

The history of neurolinguistics is described, starting with the modern period, beginning in the 1960s. Subsequently, an overview of studies and theories on the effects of brain lesions on language behavior is presented. Up to the nineteenth century, mainly single case descriptions have been recorded. Franz Joseph Gall stimulated the search for the localization of mental functions in the brain, in particular language. Originally, language was primarily viewed as a production and perception of words. In the twentieth century, aphasiologists began to investigate syntactical and phonological issues in relation to aphasia. Interest in linguistic aspects of language resulted in the emergence of neurolinguistics as a scientific discipline.

Birth

Levelt (2012) has written an extensive and insightful history of psycholinguistics. A remarkable feature of this history is that it pertains only to the *pre-Chomskyan* period: it ends with Chomsky's opposition to Skinner's behavioristic explanation of language behavior (Chomsky, 1959). Most psycholinguists would argue that, feat actually marked the *beginning* of psycholinguistics. Levelt argues that the psychology of language has a long history, starting at the end of the eighteenth century, concerns various domains of research, including also the study of the consequences of localized brain lesions on language or aphasiology in the nineteenth century. In a similar way, the birth of neurolinguistics as a scientific discipline in the 1960s should not be considered as the beginning of something completely new. As with psycholinguistics, there is a very long history, going back to antiquity, of scholars writing about language and the brain, or rather language impairments following brain disorders; it overlaps to a large extent with that of psycholinguistics. This historical overview will therefore deal more extensively with the period *before* neurolinguistics 'officially' emerged around the 1960's, than the time since its 'birth'.

While Chomsky's review of Skinner's book is for many the marker of the birth of psycholinguistics, there is no precise, commonly recognized starting point for neurolinguistics. Chomsky's publications probably played an important role as well, be it indirectly by stimulating researchers to incorporate linguistic notions in their study of language disorders, in particular of aphasia. One could say that neurolinguistics emerged, due to various attempts to provide the study of language disorders a stronger theoretical basis. That neurolinguistics was not a completely new discipline, but rather the continuation of the various disciplines involved in the study of language and the brain, was evident to the founders of 'modern' neurolinguistics.

Eric Lenneberg (1960) in a book review of Penfield and Robert's (1959) well-known *Speech and brain mechanisms* (see below) introduced the term *aphasiology* to indicate the field of study that 'has been with us *de facto* for a good hundred years'. Edith Trager (1960) mentioned Lenneberg's proposal, but suggested the term *neurolinguistics* for the interdisciplinary field of research, the substance of which was the relationship between the human nervous system and language. Dingwall and Whitaker (1974) in their review of the literature, titled *Neurolinguistics*, simply referred to Trager's definition of the area and discussed studies in different sections: studies on the localization of language functions and studies on neurological and linguistic analysis of aphasia. A third section was called *manipulative studies of brain function*, dealing with different methodologies of examining the central question, such as neurosurgical studies, split brain studies, pharmacological deactivation, and electrical stimulation of the brain. Interestingly, they noted that some years earlier, an attempt had been made to introduce the term *biolinguistics*, but it failed to gain acceptance. A journal with that title started in 2007 (Boeckx and Grohmann, 2007) and the core questions apparently are more or less the same as those of neurolinguistics in the 1970s.

David Caplan (1987) wrote the first comprehensive introduction to the emerging fields of neurolinguistics and linguistic aphasiology (see **Figure 1**). This distinction indicates that neurolinguistics encompassed more than aphasiology. Neuroimaging studies, examining patients and healthy individuals,

Figure 1 David Caplan.

were quickly becoming popular. He distinguished between four 'forms of arguments' that are relevant for developing a theory on language and the brain: (1) arguments from linguistics and psycholinguistic structures to neural structures; (2) arguments from neural structure and function to the nature of language and neural processing of language; (3) arguments from parallel structures; and (4) analysis of the results of disease of the brain. Furthermore, he described five techniques of study in neurolinguistics: (1) stimulation of the brain; (2) recording neurophysiological correlates of language; (3) lateralized stimulus presentation; (4) anesthetization of a single hemisphere (i.e., the Wada test; see below); and (5) metabolic scanning (i.e., blood flow scanning). This list illustrates that although aphasiology and neurolinguistics deal to a very large extent with the same issues, there is more under the sun than aphasic patients that can provide answers concerning the relationship between language and the central nervous systems. In particular, the technical developments concerning the various brain imaging techniques have played a crucial role in the last two decades and dramatically changed the situation: aphasia was practically the main source of information for centuries, but we can now examine the core question *in vivo* in intact human individuals in a very controlled way, looking at reliable functional changes occurring within milliseconds and in very small regions.

Neurolinguistics as a Scientific Discipline

A defining feature of a discipline is the existence of written records, in particular handbooks and scientific journals. The American Harry Whitaker, trained as a linguist, played a key role in this process (see **Figure 2**). As an editor he started a book series entitled *Perspectives in Neurolinguistics and Psycholinguistics*, 27 volumes large, dealing with various issues, such as neurolinguistics, lateralization, development, and bilingualism. He was also the founding editor of the journal *Brain and Language*, introduced in 1974. The interdisciplinary study of brain and language was the central motive for starting this journal. With Brigitte Stemmer, Whitaker edited the *Handbook of Neurolinguistics* (1998), which opened with a chapter on the history of neurolinguistics from his hand. And the modern development is reflected in the *Handbook of the Neuroscience of Language* (2008) from the same editors.

The *Journal of Neurolinguistics* was founded in 1985 by Fred Peng. Not much later, in 1987, Chris Code and David Muller started the journal *Aphasiology*. Looking at the editorial statements, it seems that the *raison d'etre* of these journals was not a new area of scientific questions, but rather the need for publishing a large number of *interdisciplinary* articles, for which apparently there was not enough room in more neurologically oriented journals, like *Brain*, or more general journals like *Neuropsychologia* or *Cortex* (in which studies on language and the brain also have been published).

Russian Roots

One major root of the 'new' field of neurolinguistics lies in the United States, in particular the Boston Aphasia Unit, established by the neurologist Norman Geschwind (1926–84) and the psychologist Harold Goodglass (1920–2002) (see below). A second root originated in Russia. According to a communist view, everybody is equal and has equal chances, given the proper environmental circumstances. Lev Vygotsky (1896–1934) formulated a developmental psychology based on this fundamental assumption. Language plays a crucial role in this system, as it provides the means of social communication. Alexander Luria (1902–77; see **Figure 3**) adopted Vygotsky's views and applied these in his work as a clinical neuropsychologist. His vast experience with individuals with brain lesions allowed him to develop his well-known model of the working of the brain (Luria, 1973). According to this model, language acts as a control mechanism: it is used to regulate and

Figure 2 Harry Whitaker.

Figure 3 Alexander Luria.

organize behavior. The study of language disorders was very important for understanding human behavior and Luria described his ideas in his *Basic problems of neurolinguistics* (1976). However, linguistics here did not refer to anything like Chomskyan principles (Buckingham, 2007). On the contrary, it was based on the Aristotelian association principles that had also been used in the classical conditioning theory, developed by the Russian physiologist Ivan Pavlov (1849–1936).

Finally, the Russian linguist Roman Jakobson (1896–1982) was a contemporary of Vygotski and Luria and they most likely knew each other (Akhutina, 2003). He settled in the United States in 1941. He applied his linguistic ideas on language development in children also to aphasia (Jakobson, 1941). He relied on Kurt Goldstein's descriptions of aphasic phenomena, but argued that they should be analyzed within a linguistic framework, specifically the structuralist approach from Ferdinand de Saussure, rather than the holistic psychological framework. Jakobson's work played an important role for the introduction of linguistics in aphasiology in the United States, specifically in the analysis of phonological disturbances (Blumstein, 1973; Friedrich, 2006).

We have witnessed the rise of many 'new' disciplines since the 1960s, many carrying the prefix 'neuro' (for instance, neuropsychology, neurolinguistics, and neurophilosophy), and there were also new branches within 'linguistics' (for instance, sociolinguistics, anthropological, and historical linguistics). However, due to the arrival of the enormous technical facilities to study, *in vivo*, structure and function of the brain, scientists of these many different strands currently collaborate under the flag of *cognitive neurosciences*. This pattern of specialization and integration indicates that what counts is the work that is done, rather than its flag. Rather than focusing on these more recent activities in the field of neurolinguistics since the 1960s, this history will deal with the description and analysis of language disorders. First, the history of aphasia will be described. Subsequently, the issue of hemispheric differences will be discussed, followed by a number of related issues. The emphasis will be more on the various approaches, research areas, and significant milestones than on concrete findings.

Antiquity

When examining early descriptions of language disorders associated with brain lesions, it is important to realize that language was conceptualized in a different way than we currently do. The common conceptualization of mental functions was, broadly speaking in terms of perception, evaluation or judgment, and memory, also referred to as the inner senses (see also Whitaker, 1998a). Language was not a separate function in this scheme. Knowledge of words was regarded to be an aspect of memory and for centuries, language disorders that we now might interpret as aphasia were referred to as the loss of the memory for words. Only in the nineteenth century, this picture changed dramatically, but even at the end of the nineteenth century, aphasia was interpreted as simply a form of *partial memory loss (amnésie partielle)* (Sollier, 1892: p. 61).

Also the conceptualization of the brain and brain functioning was completely different from current views. Related to

Figure 4 The inner senses.

the model of the inner senses mentioned above was the *ventricular* or *cell theory*: the inner senses, representing the soul or psyche, were associated with the three ventricles in the brain (see **Figure 4**; Clarke and Dewhurst, 1996). The white matter played only a secondary role, while often the cortex was compared to the rind of a tree. The significance of the cortex became clear at the beginning of the nineteenth century and a systematic division and nomenclature of cortical regions was developed by Louis Pierre Gratiolet (1854). With this in mind, we now turn to these early descriptions of language disorders.

An early medical document is the *Edwin Smith Papyrus*, found in Egypt. It is dated from around 1700 BC, but is obviously a copy of a much older papyrus and contains 48 case descriptions and advices for physicians how to deal with particular disorders (Breasted, 1930). Among these cases, there are five with language disorders. A typical description of such a case is Case 20:

> One having a wound in his temple, penetrating to the bone, perforating his temporal bone; while he discharges blood from both his nostrils, he suffers with stiffness in his neck, he is speechless. An ailment not to be treated.
> (Breasted, 1930: p. 286)

The Egyptians adhered to the so-called cardiocentric system, implying that the soul was associated to the heart and not the brain. Although the Greek scholar Aristotle (384–322 BC) also subscribed to this cardiocentric view, many others assumed that the brain was the organ associated with the soul or mind. Among these were Plato (428–347 BC) and Herophilus (335–280 BC), who is considered by many as the father of anatomy and the founder of the above mentioned ventricular theory. While Aristotle's view on the localization of the mind was wrong, he had an enormous impact on many scientists, working in different disciplines, for many centuries. His theory of the functioning of memory, still frequently cited, is

expressed in his well-known association laws: concepts are associated because of *similarity*, *contiguity*, and *contrast*. The organization of an individual's knowledge, including language, presumably is based on these rules. Aristotle had a detailed view on language (McKeon, 1946), but it is his description of speech disorders that has been incorporated in the medical literature (Wollock, 1997). Speech was described in terms of the instruments used (lungs, air, larynx), the modulation of the noise into vowels and consonants, and a third important feature was the sequential order of sounds, reflecting Aristotle's law of contiguity. In line with this view of speech production, different speech disorders were recognized. The reduction of control over the production of speech sounds was termed *traulotes*. The absence of sounds or syllables was named *psellotes* and the incorrect connection of speech sounds, syllables, the duplication of syllables, or the lengthening of sounds was named *ischophonia*. The latter type seems to reflect what we would call stuttering. This classification has been used until the Renaissance.

In addition to these mere general descriptions of brain functioning and speech, a number of descriptions can be found in medical and nonmedical (e.g., the Bible) documents of individuals suffering from language problems (see O'Neill, 1980). However, these are purely descriptive, often very short with few details, and they usually do not reveal much from underlying notions of brain functioning or the nature of language disorders.

Renaissance

O'Neill (1980) identified a turning point at the beginning of the sixteenth century. Giovanni de Vigo's (1450–1525) *Practica Copiosa in Arte Chirurgia* (1514) contains a case of traumatic speechlessness. Similar observations were made by Giacomo de Berengario (1460–1530), Nicola Massa (1504–89), William Clowes (1540–1604), Hieronymus Mercurialis (1530–1606), and Johann Schenck von Grafenberg (1530–98). These works reflect a shift in medicine during the sixteenth century from mere description toward an analysis of mental functions in relation to the brain, a change presumably due to the fact that physicians started to register their own anatomical observations, rather than relying on classical texts.

Benton and Joynt (1960; see also Benton, 2000) reviewed Renaissance descriptions. Two cases from the seventeenth century, from Johann Schmidt (1624–90) in 1676 and Peter Rommel (1634–1708) in 1683, attained a level of analysis that was superior to those that had hitherto appeared. Schmidt noted that his patient substituted one word for another, that he could not recognize letters or read words, but that he was able to write to dictation. Rommel (1683) presented his case under the title *On a rare aphonia*, apparently surprised by the fact that his patient could not speak spontaneously but could still recite her prayers, an early description of a dissociation between voluntary and automatic speech. The Swiss physician Johannes Jakob Wepfer (1620–59) collected his observations in several works, notably *Observationes medico-practicae de affectibus capitis internis & externis*, posthumously published in 1727 (Luzzatti and Whitaker, 1995). At least 13 cases showed a clear language disorder, which Wepfer described as the loss of memory. In point of fact, the classical authors typically interchanged the terms 'memory' and 'language' (the latter always to be understood as speech or expressive language).

Giovanni Battista Morgagni's (1682–1771) famous *De sedibus et causis morborum per anatomen indagatis* (Morgagni, 1762) contained a number of cases of speechlessness associated with apoplexy and head trauma. He frequently indicated that although the patient could not speak, he was able to understand spoken language. Indeed, in none of his cases a speech comprehension deficit is observed. It should be noted that a specific speech comprehension deficit was not recognized as such until the late 1860s; comprehension problems were interpreted as intellectual deficits (see also Boller, 1978). Morgagni, like Wepfer, observed on many occasions the occurrence of a speech problem in the presence of a *right-sided* hemiplegia and a lesion in the *left* hemisphere.

The first major work devoted to the subject of aphasia was Johann Gesner's (1738–1801) chapter *Die Sprachamnesie*, in volume 2 of his *Samlung von Beobachtungen aus der Arzneygelahrtheit* (Gesner, 1770; Luzzatti, 2002; see **Figure 5**). Gesner tried to analyze the nature of the impairment more precisely and concluded that it consisted of an inability to associate images or abstract ideas to their expressive verbal symbols. Gesner's theoretical analysis is a first attempt to provide a functional explanation of aphasia. A somewhat similar attempt was made by Alexander Crichton (1763–1856) also attempted to use speech disorders as a means to understand underlying mental processes and impairments. Like Gesner, he suggested that aphasia may be regarded as a very singular defect of (verbal) memory, specifically, "a defect of that principle by which ideas, and their proper expressions, are associated" (Crichton, 1798).

Figure 5 Johann Gesner.

The Nineteenth Century

The study of language and the brain changed dramatically in the nineteenth century. The German physician Franz Joseph Gall (1758–1828; see **Figure 6**) originally studied the anatomical structure of the brain. He then decided to analyze *human nature* in relation to the brain. He formulated a number of principles that together implied the notion of localization of faculties or *organs* of mental functions: he believed that faculties were inborn and every faculty had its own place on the cerebral cortex. Next to his revolutionary (heretic, according to many) view on localization of the mind, he also had different view on mental functions. He did not believe in a unified mind, the *res cogitans*, like Descartes, but argued that faculties were naturally acquired mechanisms to interact with the world; there are various lower order faculties, important for survival, and other functions, relevant for interaction and communication and these also cause the individual differences in character. These faculties must be inferred by systematic examination, they cannot be defined deductively. One way to collect supportive evidence for the existence of specific faculties was to find 'bumps' on the skull systematically associated with specific well-developed faculties, in humans as well as in animals. Another useful approach was to study the consequences of focal lesions on mental faculties. The study of the localization of lesions leading to language disorders became the prototypical case in this discussion on localization of function. Gall (1822–1825) himself argued that there were two areas associated with language, situated in the cortex just behind the eyes, one area responsible for language in general and the other for the memory of words.

The physiologists in Paris opposed heavily against Gall's localization theory, in particular Jean Pierre Flourens (1794–1867) in his *Examen de la Phrenologie* (1842). However, Jean-Baptiste Bouillaud (1796–1881) used this latter approach, which was referred to as the clinicoanatomical method, to argue that Gall's *principle of localization of faculties* was essentially correct: based on an analysis of lesion sites of aphasic patients language appeared to be localized in the anterior part of the brain (a more systematic classification of lobes, gyri, and sulci was only developed around the 1850s). Bouillaud's (1825, 1848) attempts were not really successful, until Paul Pierre Broca (1824–80) presented the case of a patient, *monsieur Leborgne* and nicknamed *Tan* after the syllable he used to communicate, to members of the Anthropological Society (Broca, 1861; see **Figure 7**). Only recently Domanski (2013) was able to reveal some biographical details of *monsieur Leborgne*.

Within a period of 4 years, and on the basis of a limited number of patients, Broca convinced many of his colleagues that a very specific mechanism, the memory for the articulation of words, was situated at the foot of the third frontal gyrus, and only in the left hemisphere (Harris, 1991). Broca assumed that the language faculty consisted of several layers of processes, from a general faculty to use language to more specific faculties to express oneself in a specific modality: speech, writing, and gesticulation (see Eling, 1984). A detailed description by Dominique Larrey (1814) of a patient, with a language disorder similar to that of Tan, and a verified postmortem localization of the lesion in the left frontotemporal region had gone unnoticed: the time was not ripe (Feinsod and Aharon-Peretz, 1994).

The next step was taken by the German physician Carl Wernicke (1848–1905; Eggert, 1977). Having analyzed the pathway of nerve fibers from the ear to the temporal cortex, he looked for patients with an impairment in understanding language (Wernicke, 1874; see **Figure 8**). For Broca, *aphemie* (the term aphasia was introduced by Armand Trousseau (1864) and generally accepted) implied an inability to articulate words, while intelligence and comprehension are intact. Wernicke argued that there are also patients with a severe problem in understanding language. The lesion responsible for this condition would be situated in the temporal lobe. Wernicke then went one step further: he argued that there are language *centers*: centers with word images, images for recognizing spoken words, for speaking words, but also for reading and writing words. (This switch from faculties to centers has never been analyzed and

Figure 6 Franz Joseph Gall.

Figure 7 Paul Broca.

Figure 8 Carl Wernicke.

Figure 9 Heymann Steinthal.

clarified.) These centers are also interconnected: an interruption of the connection, a disconnection of the center for understanding words and the center for speaking words results also in a language disorder, conduction aphasia, where patients can understand and speak more or less normally, but they have problems repeating sentences spoken to them.

The German psychiatrist Carl Finkelnburg (1832–96) in 1870 (see Duffy and Liles, 1979) also opposed the idea that in aphasic patients only speech is affected. He described five cases and argued that in most cases different forms of language production (speech and writing) and language perception (hearing and reading) are involved, essentially all processes that convey meaning through learned sensory signs – that is through symbols. He spoke of the symbolic faculty or the *facultas signatrix* as it was termed by the German philosopher Immanuel Kant.

While Wernicke is traditionally regarded as the person who introduced the idea of a language system, consisting of centers and their interconnections, the English physician Henry Charlton Bastian (1837–1915) had developed a rather similar diagram in 1869. Lorch (2013) has shown that his model, and in particular his clinical protocol for analyzing the nature of language disorders in various modalities had been very influential for many decades in England.

Developing diagrams, based on the analysis of intact and impaired language functions, became a popular activity among students of the brain. The site of the lesions was frequently a point of discussion and could only be verified postmortem and this information was therefore not always available. Few words were spent on the psychological theory of language used in these studies.

There were a few important exceptions, for instance, the German linguist Chajim Steinthal, the German internist Adolf Kussmaul, and the English neurologist John Hughlings-Jackson. Steinthal (1823–99; see **Figure 9**; see Eling, 2006) has been called the first psycholinguist. Unlike his fellow linguists who focused on comparative linguistics, he was also interested in language as a psychological process and developed a theory of producing and understanding an utterance. Having formulated the first psycholinguistic theory (Steinthal, 1871), he demonstrated the usefulness of it in an appendix in which he applied his ideas to aphasia. An important point was his differentiation between *aphasia* and *acataphasia*. In aphasia, the problem is at the word level, a word memory retrieval problem, while acataphasia refers to a problem at the sentence level, the relation of words among each other, representing the actual meaning of the utterance. His theory was rejected by physicians in Berlin, arguing that he had no knowledge of aphasic patients.

In contrast to Steinthal, Adolf Kussmaul (1822–1902) was respected by his colleagues and his monograph on *Sprachstörungen* (1877) was regarded as probably his best scientific contribution. While Wernicke stressed the need to localize centers in the brain, Kussmaul focused on language as a functional system and his model is a (psychological) process model, not a neuroanatomical model. Like Wernicke he distinguished different modalities. But he also distinguished between levels of language, referring to Steinthal (Levelt, 2012). He distinguished between disorders of articulation (*dysarthria*) and cortical language disturbances, which he subdivided in *dysphasias* or aphasias (real language problems) and *dyslogias* or *dysphrasias* (due to intelligence problems). Kussmaul introduced the notion of *agrammatism*, referring to grammatical problems and here also he distinguished various forms: aphasic acataphasia (omission of words in a sentence), grammatical acataphasia (which we would now refer to as telegraphic speech), and syntactic aphasia and we would call that paragrammatism, the combination of sentences or sentence fragments. However, Kussmaul's ideas on sentence processing were not generally adopted by his colleagues at that time. His model on word processing, however, was cited frequently.

Jackson (1878) did not subscribe to models that localize language centers, arguing that *to localize a symptom is not the same*

as localizing a function. Moreover, he indicated that the fundamental unit of analysis should not be a word, but a *proposition*. His opposition against strict localization was important, but he himself did not formulate a psychologically or linguistically oriented framework to explain aphasic symptoms.

The Twentieth Century

The first half of the twentieth century can be characterized by the opposition to the rather simplistic localization approach, in two ways with Pierre Marie (France; see **Figure 10**), Von Monakov (Switzerland), Goldstein (Germany), and Head (England) as key figures. First, the idea of strict localization was contested. Brain areas are interconnected and the brain functions more as a whole than as a set of specialized functions. Although this argument against the localizationist approach sounded plausible, it did not lead to a new and more productive description of the functioning of the brain. Secondly, language or rather communication was more than words, to study the relation between language and the brain by associating words to brain regions, would be to miss a crucial feature of language, the meaning of an utterance based on the relations among words and word forms. This approach is usually characterized as *holistic*. The contest between the parties led to the famous *Aphasia Discussion* in Paris in 1908 (Lecours et al., 1992). This development is illustrated in various ways (see York, 2009).

A number of scholars studied grammatical problems in the beginning of the twentieth century. Among these were Arnold Pick, Karl Bonhoeffer, Karl Kleist, Kurt Goldstein, Erich Salomon, and Max Isserlin. Henry Head, Hughlings-Jackson's pupil and successor, was familiar with this work and referred to them as the *psychological school* (Howard, 1985).

The German–Hungarian neuropsychiatrist Arnold Pick (1851–1924; see **Figure 11**) broke with the associationistic tradition of Wernicke and adopted the approach developed by Oswald Külpe in Würzburg, also known as *Thinking Psychology*. Karl Buhler (1897–1963), also working there, attempted to identify different stages in thought formulation on the road from thinking to speech, which culminated in an early textbook on psycholinguistics: *Sprachtheorie* (Language Theory, 1934). Pick had collaborated with Buhler, and he used these ideas to analyze speech problems in aphasic patients. One of his first papers was on agrammatism (Pick, 1898), the most comprehensive formulation of his theory of speech production in aphasia appeared posthumously in 1934 (Pick, 1931; see De Bleser, 1987 for an extensive discussion).

Figure 11 Arnold Pick.

Figure 10 Pierre Marie.

Henry Head (1861–1940) played a prominent role in England, first by promoting Hughlings-Jackson's work, secondly by criticizing many of the early aphasiologists by calling them *diagram makers*, and thirdly by presenting his view on aphasia in his two-volume monograph *Aphasia and Kindred Disorders of Speech* (Head, 1926; Jacyna, 2005). Head assumed that in some sense, aphasia was also a disorder of intelligence, though not general intelligence but of thought as far as it depends on language. He distinguished between *verbal, syntactical, nominal,* and *semantic defects*. A verbal defect is primarily characterized by a problem in finding the right words; understanding of individual words and simple sentences is intact. A syntactic defect is characterized by a severe problem with rhythm and syntax. The patient may speak rather quickly, produces jargon, prepositions, conjunctions, and articles may be omitted. A nominal defect is not a pure linguistic phenomenon; the patient can produce all sorts of words, but has difficulty to find the right words for what he wants to say. A semantic defect occurs when a patient fails to understand the full significance of words and phrases. These categories represent theoretical entities

that rarely occur in a pure form in clinical cases. Clealry, Head's criticism of the classical aphasiologists has had a greater impact than his new taxonomy.

The German neuropsychiatrist Kurt Goldstein (1878–1965), who emigrated to the United States in 1935, rejected the theory and classification of his teacher Carl Wernicke, and was influenced by the Gestalt psychology, becoming popular at that time (Eling, 2012). Brain lesions result, according to Goldstein, in problems with *abstraction*: the concrete features of the situation determine perception and thought. Patients may also suffer from catastrophic reactions and their language behavior may also reveal attempts to readjust. Although this approach was sympathetic because of its emphasis on the patient as a person, it had little explanatory power and could not simply be tested in an objective manner.

Perhaps Head was quite correct when he judged the situation in the middle of the twentieth century as *chaos*. In contrast to the two theoretical camps, on the one hand the rather strict localizationist and associationist approach started by Wernicke and the more global, holistic, psychological approach of Pick, Goldstein, and Head, a new approach was tried in the United States by the neurologist Theodore Weisenburg (1876–1934) and the psychologist Katherine McBride. They studied aphasia from a clinical point of view, collected data from large numbers of aphasic patients on a battery of subtests, addressing various modes of language behavior. On the basis of these kinds of observations, they suggested that patients could be classified as predominantly expressively disturbed, receptively, mixed, or as amnestic. This approach, however, was not convincing from a theoretical point of view.

The chaotic situation had led to a diminished interest in aphasia in general in the middle of the twentieth century. The American neurologist Norman Geschwind early in his career became intrigued by the works of Carl Wernicke and he was convinced that the fundamental issue of relating psychological function to brain (areas) should be addressed by adopting Wernicke's approach, by looking for cortical centers and connections, or rather, *disconnections* (Geschwind, 1965a,b). Geschwind started with the psychologist Harold Goodglass at the Boston Aphasia Unit. This unit attracted the interest of many physicians and (neuro)psychologists from all over the world. This was an important factor for the development of neuropsychology in general and a specific interest in neurolinguistics as well.

Acquired Reading and Writing Disorders

Early language models, as used by, for instance, Broca and Bastian, assumed independent memory stores for word images for separate input and output modalities: for hearing and seeing a word, for speaking and writing a word. Attempts have been made to localize these centers, in particular by examining the occurrence of specific reading and writing disorders. Originally, physicians used the term *alexia* and *agraphia*; *dyslexia* (introduced by the German physician Rudolph Berlin in 1887) and *dysgraphia*, first used to refer to a *disturbance* (or a developmental problem) rather than a complete *loss* of function, have replaced these terms. Also the term *word blindness* was used frequently. In the nineteenth century, this study was hampered by the fact that reading and writing were not common in the general population. Starting with the case description of Johann Schmidt of patient with a reading problem in 1676 (see above), various other case descriptions appeared in the literature, also in the nineteenth century (Benson and Cummings, 1985). Jules Joseph Dejerine (1849–1917; see **Figure 12**) published reports of two patients, a man with alexia and agraphia and *monsieur C.*, showing alexia *without* agraphia and no difficulties with spontaneous speech (Dejerine, 1891, 1892; Bub et al., 1993 for a detailed analysis). Subsequently, Dejerine described a third form of alexia: in this type, what Dejerine called the language zone (a more general language function, encompassing the more specialized areas of Broca and Wernicke) is disrupted, resulting in a disturbance of *inner speech*. Postmortem studies indicated that the first form is associated with a lesion in the area of the angular gyrus (the store of visual word forms, necessary for reading and writing), the second form with a lesion in pathways from the special word form area to the general language area that separates it from the angular gyrus. And the third form results from cortical lesions in the language zone. Dejerine's interpretation was quickly adopted by others.

Figure 12 Jules Dejerine.

The study of reading disorders became particularly of particular interest in the context of learning problems in children without obvious neurological disorders, also referred to as *developmental dyslexia*. New interest in acquired reading disorders was aroused by the analysis of reading errors of neurological patients by John Marshall (1939–2007) and Freda Newcombe (1925–2001) (Marshall and Newcombe, 1966, 1973). Discovering different patterns of errors, they argued that reading of words may follow different routes in the cognitive system: the visual route and the phonological route. Borrowing word recognition models from psycholinguistic studies, they demonstrated the usefulness of this way of modeling functional disorders (e.g., Coltheart et al., 1980; Patterson et al., 1985) and this became a strong impetus for the rise of cognitive neuropsychology in the 1980s. In essence, these models were similar to the classical diagrams, although more elaborated and with a better empirical foundation.

Louis-Victor Marcé (1828–64) provided clinical case descriptions of patients with dissociated patterns of spoken and writing language disorders in 1856. The first description of a case of pure agraphia is from Albert Pitres (1848–1928) (Pitres, 1884; Lorch and Barriere, 2003). The localization of a writing center is commonly ascribed to Exner (1881), but actually he did not have proper empirical basis for that and only speculated about this possible localization (Roux et al., 2010). Almost all aphasic patients have some degree of agraphia and it is usually a mixture of language and nonlanguage factors (Benson and Cummings, 1985) and since pure agraphia is very rare, the phenomenon is hard to analyze.

Related Areas

Laterality

When Broca convinced his colleagues in the early 1860s that the principle of localization of function might be correct at least for some functions, he also introduced another quite revolutionary idea. He suggested that the faculty of articulated speech was restricted to the left hemisphere. Immediately, Gustav Dax claimed priority for this observation for his father, who presumably gave a lecture at a conference in Montpellier in 1836 (Finger and Roe, 1999). Another fact, suggesting an asymmetry was hand preference. Broca explicitly denied a connection between these two phenomena, but the two were almost immediately linked to each other. The general idea (formulated by Broca) was that the left hemisphere had a little advantage in development because it received blood with somewhat more oxygen. This results in a dominance of the left hemisphere and this theory was referred to as the cerebral dominance theory. According to this theory, the two hemispheres are basically identical but the left develops quicker and becomes the dominant hemisphere in which language function emerges (Harris, 1991).

The cerebral dominance theory was replaced by the hemispheric specialization theory in 1960. It was the result of a research program, undertaken by Roger Sperry, Joe Bogen, Michael Gazzaniga, and collaborators, on the consequences of the split-brain operation technique for patients with intractable epilepsy. Special experimental paradigms, for instance, the visual half-field presentation paradigm and the dichotic listening test, revealed that the right hemisphere had its own special functions. Moreover, the right hemisphere appeared to be active in language processes, although it appeared to lack grammatical functions.

Hemispherectomy

Hemispherectomy, the removal of one hemisphere under the assumption that functioning remained possible with the remaining parts of the brain, was introduced in 1928 by the American neurosurgeon Walter Dandy (Goodman and Whitaker, 1985). It has been used for children with brain tumors and severe forms of epilepsy. According to the cerebral dominance theory, specialization develops only later in life. Thus, it should be possible for the remaining hemisphere, even the right one, to acquire language. Originally, cognitive functioning after hemispherectomy was surprisingly good and language functioning at first glance seemed intact. However, more detailed studies have shown that the right hemisphere can acquire language only to some extent. Subtle syntactic deficiencies remain (Dennis and Whitaker, 1976).

Brain Stimulation

Yet another surgical procedure, used for the treatment of epilepsy, has revealed important information with respect to language representation in the brain. Focal sources of epileptic attacks often occur in the temporal lobe, close to areas that are involved in language processing. Removal of tissue to stop these attacks may be effective but the loss of language function should be prevented. Cortical stimulation is a technique, applied during brain surgery, to localize the area responsible for the epilepsy and also for exploring which areas are important for language (see Whitaker, 1998b).

Penfield and Roberts (1959) have recorded their extensive experiences with this procedure (see **Figure 13**). Similar studies were performed by Ojemann and Whitaker (1978). While highly discrete areas were found, indicative of specific language centers, a rather large variability of localization of these centers was observed among individuals.

Wada Test

Before a surgery is performed in severe cases with intractable epilepsia, a *Wada test* is performed to determine which hemisphere is primarily responsible for language. In this test, named after the Japanese–Canadian neurosurgeon Juhn Wada, each hemisphere is deactivated for a short period, that is, some minutes: language functions remain intact if the nondominant hemisphere is activated (Wada, 1997; Snyder and Harris, 1997; see **Figure 14**). The general picture arising from studies with this procedure is that language is localized primarily in the left hemisphere, even for left-handed and ambidextrous individuals. However, language functions are examined in a rather general manner and the procedure is not used for analysis of specific linguistic processes.

Figure 13 Wilder Penfield.

Figure 14 Juhn Wada.

Language and the Right Hemisphere

The various areas of research mentioned above have played a crucial role in our understanding of the complementary roles of the two hemispheres in language processes. Language disorders typically result from lesions in the left hemisphere, but subtle effects have been observed following right hemisphere lesions. Hughlings-Jackson (1864) agreed with Broca that speech was specifically associated with the left hemisphere but argued that the right hemisphere played a significant role in language as well (which is not in contradiction with Broca's position!). Importantly, Hughlings-Jackson (1874) claimed that the basic function was to propositionize, to express a message; this could be in the form of a spoken statement but it could also be expressed in the form of gesture and mime. The relation between verbal and nonverbal communication is an old one in the aphasia literature (Feyereisen and Seron, 1982a,b; Lindell, 2006). Prosody, but also aspects such as metaphorical language and the understanding of jokes, and even sign language (Corina, 1998) play a role in this discussion. Hughlings-Jackson (1878) noted that some aphasic patients could speak when they became emotional, frustrated. He also observed that speech was flat, lacked emotional tone following right hemisphere lesions. The study of the role of right hemisphere in language was specifically triggered by a paper by Monrad-Krohn (1947) who argued that the right hemisphere plays a role in emotional tone or prosody of speech. This view was triggered by analyzing the speech of a woman who recovered from aphasia but her-speech sounded like that of a German speaker. A short, similar observation had been made by Pierre Marie in 1907 and Whitaker (1982) introduced the notion of foreign accent syndrome for this clinical picture. In later years, a distinction was made between different functions of prosody: more linguistic functions (meaning, sentence structure) and emotional functions with a larger role of the right hemisphere in the latter functions (Ross and Monnot, 2008).

Bilingual Brain

Many people are able to communicate in more than one language. The study of how the second (and other) languages are represented in the brain and are affected by brain lesions is a relatively young branch of neurolinguistics. Yet, a number of case descriptions have appeared in the literature. An early paper was by Lordat (1843), describing a priest who became aphasic, lost the ability to speak French, but was able to communicate in a dialect. Michel Paradis has collected and translated these case reports published before 1935 (Paradis, 1983). The general picture arising from such aphasiological studies is that all kinds of patterns may occur: an earlier language may be lost while a later learned language may remain relatively intact and vice versa, and this also holds for patterns of recovery. Importantly, dissociations occur, suggesting that languages do not rely on the same underlying mechanisms. The representation of multiple languages in the brain can also be studied in healthy individuals. Albert and Obler (1978) provided the first overview of psychological, neuropsychological (e.g., using dichotic listening and visual half-field paradigms), and neurolinguistic aspects of bilingualism and concluded that language is represented more bilaterally in the bilingual brain than in the monolingual brain.

Modern Times

The study of language and the brain changed dramatically with the introduction of neuroimaging techniques. The techniques to represent anatomical structures as well as physiological processes improved very quickly. Extent of lesions and neural activity could be examined with great precision and in healthy subjects! However, these developments fall outside the scope of this historical overview.

Abstract

The present article investigates agrammatism from a neurological/neuropsychological perspective. Agrammatism was originally defined as 'telegraphic' speech output characterizing nonfluent types of aphasia. During the last five decades, it has been well documented that agrammatic patients frequently present impaired comprehension of syntactically complex sentences, a phenomenon known as 'asyntactic comprehension.' Although agrammatism was traditionally linked to frontal lesion loci, such as Broca's area, contemporary lesion and brain-imaging studies depict a widely distributed neural network, consisting of frontal, temporal, and parietal cortical regions, associated with syntactic processing and agrammatic performance. Possible relationships between syntactic comprehension and working memory are also discussed.

Introduction

Agrammatism is a language deficit, usually accompanying post-stroke aphasic disturbances (Agrammatism is also observed in neurodegenerative diseases, like the nonfluent variant of primary progressive aphasia (Gorno-Tempini et al., 2004, 2011). However, such syntactic deficits are related to a different neuropathological substrate and are beyond the scope of this article.), which affects processing of sentences, while word-level processing is relatively well preserved. Sentence processing difficulties are common both in speech production and comprehension. Agrammatic patients have difficulties in understanding grammatically complex sentences and tend to omit function words (such as prepositions and determiners), thus using a 'telegraphic speech.' It is usually seen in patients with Broca's aphasia, in the context of nonfluent, dysprosodic speech.

The first case of a patient suffering from Broca's aphasia with agrammatism was published decades before the introduction of both terms in *The Phrenological Journal and Miscellany*. In 1824, Alexander Hood described the case of a gardener, presented with acute right hemiplegia and language disturbances after a stroke in the left hemisphere. The patient's profile is compatible with the contemporary clinical description of Broca's aphasic syndrome. Interestingly, Hood's patient is reported to speak telegraphically, using short, simple sentences, like 'something about it' (that was his answer when asked by the doctor to describe what happened to him). Even if Hood explained the case in the context of Phrenology, today – if tested in a modern neurological clinic – this patient could be diagnosed as a patient with Broca's aphasia and signs of agrammatism. Research on agrammatic speech per se was first conducted in the early 1900s on German-speaking patients, and subsequent studies with English-speaking patients with aphasia established the hallmark of the deficit to be omission of function words (Miceli, 2003). This is still considered to be one of the fundamental characteristics of agrammatism in contemporary clinical practice. Further support on this notion has been provided by analyses of agrammatic patients' connected speech (e.g., Rochon et al., 2000; Saffran et al., 1989) showing that the main symptom of agrammatic speech is the use of ungrammatical utterances due to omission (or substitution, depending on the language) of grammatical morphemes, both bound and free, such as verb inflection, determiners, and prepositions. Below is a speech sample of a chronic aphasic patient which was assessed in our clinic:

> […] much drink, eh? No, drink, much drink, eh, and then, ah, eh, stress, that's why I can't talk now, stress and I can't talk, after better now, but I stress and I can't talk […].
>
> translated from Greek

The patient (FS) is a male 49-year-old worker, with 9 years of formal schooling. He suffered a stroke 8 years ago, resulting in acute right hemiplegia and severe nonfluent aphasia. The brain lesion included the middle and inferior frontal gyrus, the precentral gyrus, the supplementary motor area, and the insula (Figure 1). During recovery, he regained his motor and every-day communicative abilities to an adequate degree, but the agrammatic pattern remained. As can be seen from the above sample, his speech completely

Figure 1 FS's lesion.

 http://dx.doi.org/10.1016/B978-0-08-097086-8.54022-7

lacks morphosyntactic structure. Verbs and pronouns were omitted and the meaning is almost exclusively conveyed by content words. A similar pattern was observed in his writing. FS could sufficiently write single words by dictation, but failed to form grammatically correct sentences when asked to describe an image within a short paragraph. Finally, he had difficulty in understanding syntactically complex sentences, such as *wh*-questions and passive sentences.

Based on the above clinical example, one could claim that agrammatism affects both production and comprehension. Since the seminal paper by Caramazza and Zurif (1976) it has been well documented that agrammatic patients have difficulties comprehending syntactically complex sentences (Such deficits are not generic, in the sense that comprehension is not globally compromised. When assessing a patient with impaired comprehension, a clinical neuropsychologist should be able to differentiate between impairment of syntactic abilities and other processing deficits. For example, patients with conduction aphasia often show impaired comprehension, but this can be attributed to a phonological WM deficit, while syntactic abilities remain intact (Gvion and Friedmann, 2012).), that is semantically reversible sentences that involve movement out of the object position, such as sentences presented in (1) below.

(1) a. [***Which girl***]$_1$ did the boy kiss t$_1$?

b. [***The girl***]$_1$ that the boy kissed t$_1$ was tall

c. It is [***the girl***]$_1$ that the boy kissed t$_1$

(2) a. [***Which boy***]$_1$ t$_1$ kissed the girl?

b. [***The boy***]$_1$ that t$_1$ kissed the girl was tall

c. It is [***the boy***]$_1$ that t$_1$ kissed the girl

Several cross linguistic studies, using sentence-picture matching, truth-value judgment, or/and grammaticality judgment tasks, have shown that patients' performance on these sentences is at chance level; patients are unable to correctly assign thematic roles to the arguments in half of the cases. When processing sentences like (1), for instance, patients are unable to understand who is doing the kissing. On the other hand, when they process semantically reversible sentences that involve movement out of the subject position, such as sentences in (2), their performance is above chance level. This dissociation is known as 'asyntactic comprehension' and has attracted most of the recent research in aphasia.

A number of linguistic theory-driven accounts have been put forward to explain agrammatic speech production and comprehension. Some researchers have suggested that language impairments in agrammatism stem from loss of core linguistic knowledge (representational accounts), whereas others have suggested that deficits in language processing is due to reduced working memory capacity in these patients (processing accounts). In this article the focus will be on agrammatism as a processing deficit within a neurological/neuropsychological framework. Representational accounts are discussed in Grodzinsky (1990, 2000), Friedmann and Grodzinsky (1997), and Wenzlaff and Clahsen (2004) among many others.

The Neurological Correlates of Agrammatism: Evidence from Lesion Studies

Despite the fact that detailed descriptions of lesion loci can be very informative, several papers on agrammatism do not report patients' lesion sites. Other studies give us a general idea of lesion sites, providing just a vague description of patients' lesion loci (e.g., Hanne et al., 2011). Especially for studies with small sample size, individual data such as lesion locus is considered essential in order for the reader to have an idea with regard to the homogeneity of the experimental group. Moreover, reporting brain lesion information in agrammatism research papers could provide useful insight on the possible brain-function relationship, when it comes to syntactic processing.

From studies that include lesion data it could be argued that it is usually patients with Broca's aphasia who demonstrate syntactic deficits (Ardila, 2012; Basso, 2003; Benson and Ardila, 1996; Caplan, 2003a; Goodglass, 1993; Kertesz, 1985; Marshall, 2011). This observation provided support for a localizationist view, according to which, different aspects of syntactic comprehension are localized in distinct areas of the left perisylvian cortex (see, for example, the Trace Deletion Hypothesis by Grodzinsky, 1990). It should be although noted that the lesion of such patients is never restricted to the foot of the third frontal convolution. Even the famous Monsieur Tan, the patient originally described by Pierre Paul Broca, had a rather large brain lesion that affected various cortical and subcortical areas (Broca himself acknowledged that the lesion was not restricted to the posterior part of the inferior frontal gyrus, although he claimed that Leborgne's aphemia was due to the destruction of the particular area (Broca, 1861).) (Dronkers et al., 2007; Signoret et al., 1984). Clinical research has clearly shown that a lesion restricted to BA44 is not sufficient to produce a Broca's aphasic syndrome (Mohr et al., 1978). Furthermore, there have been reported patients with Broca's aphasia, whose lesion spared the inferior frontal gyrus (Nespoulous et al., 1988; Basso et al., 1985; Kasselimis et al., 2012). It has also been claimed that syntactic abilities are not likely to be localized exclusively in Broca's area, even though higher level syntactic processes may be supported by the anterior perisylvian areas (Grodzinsky, 2000). In addition, it has been recently argued that lesion-analysis techniques used in studies supporting the localizationst framework are inadequate (Caplan et al., 2007). Apart from that, as mentioned above, there are several studies involving agrammatic patients that do not report lesion data; based on contemporary aphasia literature, one cannot simply assume that a nonfluent patient's lesion will include the inferior frontal gyrus. Moreover, syntactic deficits are present in other than Broca's aphasic syndromes (Grodzinsky and Finkel, 1998; Schwartz et al., 1987; Shapiro et al., 1993; Zurif and Caramazza, 1976; Berndt et al., 1996; Dick et al., 2001; Caplan, 1987a; Caplan et al., 1985). Finally, as it will be discussed below, agrammatic phenomena occur after various lesion sites throughout the perisylvian cortex.

Even if there isn't a distinct brain region specialized for syntax, several studies have pointed to specific areas of the left hemisphere which are involved in syntactic processing. Damage to Broca's area often result in agrammatic disturbances (Basso, 2003; Biran and Friedmann, 2012; Caplan, 2003b; Carreiras et al., 2012; Grodzinsky, 2000). However, lesions producing

syntactic deficits are not restricted to the inferior frontal gyrus. Several studies report agrammatic patients with lesions in the insular cortex, in temporoparietal and frontotemporal areas, as well as in subcortical tissue (Biran and Friedmann, 2012; Borovsky et al., 2007; Christiansen et al., 2010; Thompson et al., 2010; Ruiter et al., 2010; Peristeri et al., 2013; Fyndanis et al., 2010). It should be also noted, that if a post-stroke agrammatic patient's lesion does involve a specific area, such as BA44 or BA45, that does not mean that the syntactic deficit is due to damage in the particular area, nor that the lesioned area supported syntactic processing premorbidly. In a recent lesion study, Newhart et al. (2012) investigated the relationship between various brain areas and sentence comprehension. Their results indicated that asyntactic comprehension is associated with lesion at the angular gyrus, rather than BA44. Borovsky et al. (2007) recently published a paper on lesion correlates of speech production deficits. Although they concluded that lesions in the inferior frontal gyrus were related to impairment of both fluency and complexity, they could not provide robust evidence for a specific syntactic capacity of this particular brain region, since it was not specifically involved in complex speech production over fluency. Dronkers et al. (2004) failed to find significant correlations between lesion in Broca's area and measures of syntactic comprehension. Their results indicate that other brain areas, namely BAs 22, 39, 46, and 47, are crucial for processing highly demanding sentences, such as object-clefts, object- and subject-relative clauses, while the middle temporal gyrus may be involved in word-level comprehension. Research on treatment-induced aphasia recovery is in accordance with the notion that syntactic comprehension can be subserved by several cortical areas. Thompson et al. (2010) recently showed that rehabilitation of agrammatic patients is in parallel with a shift in their brain activation pattern toward angular gyrus and superior temporal lobule, thus indicating that these cortical regions can be recruited for processing complex syntactic stimuli. In their study, Tyler et al. (2011) assessed 14 aphasic patients with a syntactic ambiguity judgment task, and found that the integrity of the pars triangularis (in Brodmann's terms: BA45; the anterior part of the Broca's area) and the posterior part of the middle temporal gyrus is essential for syntactic abilities. The authors concluded that these two areas may be functionally related in the context of a neural network that supports syntactic computations. Caplan et al. (1996) studied 18 left-hemisphere damaged aphasic patients, in order to investigate possible relationships between lesion characteristics (locus and volume) and type or degree of syntactic deficits. Their findings showed that patients with anterior and posterior lesions could not be differentiated based on performance on measures of syntactic comprehension. Moreover, no correlation was found between the severity of syntactic impairment and lesion size. The authors conclude that "the complete picture is consistent with the models proposed by Mesulam (1990) and Damasio (1992), which involve both distributed and localized features" (Caplan et al., 1996, p. 946). More recently, Caplan et al. (2007) conducted a study using far more refined neuroimaging methods and a larger patient sample (42 post-stroke aphasic patients), in order to elucidate lesion-deficit correlations with regard to syntactic processing. According to their results, performance of measures of syntactic ability is dependent on perisylvian, as well as nonperisylvian (such as the anterior part of the inferior temporal cortex and the superior parietal lobule) lesion loci. Furthermore, patients with equivalent task performance had lesions of different sizes, and patients with similar lesion volume were characterized by great variability with regard to their syntactic processing abilities. Based on these data, the authors support a notion originally introduced as the "individual variability model" (1987a,b). According to this proposed framework, sentence comprehension and syntactic processing are not invariantly localized in one cortical area. Alternatively, it is suggested that these functions are related to multiple perisylvian and nonperisylvian areas that are not similar in terms of neither cytoarchitectonic features nor patterns of connectivity, and that such relations may differ among individuals (Caplan et al., 2007).

Overall, lesion studies point to several perisylvian areas, which are considered essential for syntactic processing. Even if agrammatism is considered to be the hallmark of Broca's aphasia, the crucial brain region for a possible syntax breakdown in case of brain damage extends beyond pars triangularis and pars opercularis of the inferior frontal gyrus, and includes several other cortical areas, such as the angular, the supramarginal, and the superior temporal gyri (Caplan, 2003b). The general image emerging from modern neuropsychology research depicts a possible neural network consisting of frontal, temporal, and parietal cortical regions that supports a rather complex linguistic function: syntactic processing.

The Neurological Correlates of Syntactic Processing: Evidence from Imaging Studies

The corpus of lesion studies' literature suggests that agrammatism is usually caused by damage in the left hemisphere (It should be although noted that brain-imaging studies also provide evidence of right-hemisphere activation during syntactic processing in healthy individuals (Just et al., 1996; Moro et al., 2001; Waters et al., 2003).), including but not limited to Broca's area. The fact that agrammatic patients have difficulties processing complex sentences, such as object-relative clauses, object-clefts, and object *wh*-questions, may suggest that Broca's area has a functional role in processing such sentences (see Swinney and Zurif, 1995; Swinney et al., 1996; Zurif et al., 1993). This has been actually supported by imaging studies with nonbrain-damaged adults. Functional brain-imaging studies using a variety of tasks have created a rich picture, which indicates that sentence processing (hence, syntactic processing) taxes Broca's region (Caplan et al., 2000; Just et al., 1996; Friederici et al., 2003; Hashimoto and Sakai, 2002; Heim, 2005; Meltzer et al., 2010; Thothathiri et al., 2012; Tyler et al., 2011).

Nevertheless, the specifics of the relationship between Broca's area and syntactic processing remain highly disputed. Some researchers have claimed that the renowned foot of the third frontal convolution has a general, linguistically nonselective role; it supports a domain-general verbal or syntactic Working Memory (henceforth WM), associated with assigning syntactic structure to a sentence – especially when that

sentence include intrasentential dependencies – and using that structure to determine sentence meaning. Caplan and his colleagues have conducted several PET studies that support this *Generalist* (The term *Generalist* view, as well as *Specifist* view that will appear later, has been introduced by Santi and Grodzinsky (2007).) view (see Caplan et al., 1998, 1999; Caplan and Waters, 1999; Stromswold et al., 1996). Specifically, they have tested normal adults while making plausibility judgments about simple subject-relative clauses (e.g., *The award thrilled the actress that praised the producer*) and more complex object-relative clauses (e.g., *The actress that the award thrilled praised the producer*). Their main finding was that regional cerebral flow (rCBF) was increased in Broca's area (particularly in the pars opercularis) when participants judged the semantic plausibility of the object-relative clauses, which are syntactically more complex, compares to subject-relative clauses, which are syntactically less complex (see also Just et al., 1996). These results have led to the view that increased activation in Broca's area is due to increased syntactic processing (i.e., processing syntactically complex sentences).

Recent fMRI studies have compared processing of complex movement-derived sentences with processing of sentences that are still complex, in terms of the length, but include no movement operation. This contrast has shown that greater activation within Broca's area is associated only with processing complex movement-derived sentences (Ben-Shachar et al., 2003, 2004; Friederici et al., 2006; Grodzinsky, 2000, 2005; Kluender and Kutas, 1993; Santi and Grodzinsky, 2007; Zurif et al., 1993). For instance, Ben-Shachar et al. (2003) designed an fMRI study in which 12 healthy native speakers of Hebrew judged the grammaticality of object-relative clauses (e.g., *I helped the girl that Mary saw in the park*) and sentences with embeddings (e.g., *I told Mary that the girl ran in the park*). Their findings demonstrated a movement-related activation within Broca's area. This has been replicated in a later study (Ben-Shachar et al., 2004), in which they contrasted processing of object *wh*-questions (e.g., *What have you forgotten?*) with processing of yes/no questions that in Hebrew do not require movement (e.g., *Have you forgotten?*). In another fMRI study, Santi and Grodzinsky (2007) compared processing of object-relative clauses with processing of sentences that included a reflexive (e.g., *John knows that Mary pinched herself*). In order to assign meaning to the reflexive (i.e., *herself*), a dependency between the reflexive and its antecedent (i.e., *Mary*) should be created. This dependency is very similar to the dependency between a moved constituent and the position from which it has been moved in movement-derived sentences. Having said that, Santi and Grodzinsky found increased activation within Broca's area only when processing movement-derived sentences. Taken together, these findings suggest that the functional role of Broca's area in WM and sentence processing is more specific (*Specifist* view); Broca's area is entrusted with handling movement.

However, Broca's area is not the only cortical part involved in syntactic processing. Several brain-imaging studies point to a widely distributed network associated with comprehension of syntactically complex sentences within the left-hemisphere cortex, which includes frontal, parietal, and temporal cortices (Ardila, 2012; Ben-Shachar et al., 2003; Caplan, 2001; Caplan et al., 1998, 2001; Cappa, 2012; Crinion et al., 2006; Dronkers et al., 1994; Friederici, 2011; Humphries et al., 2005; Iijima et al., 2009; Just et al., 1996; Kaan and Swaab, 2002; Mazoyer et al., 1993; Moro et al., 2001; Röder et al., 2002; Santi and Grodzinsky, 2007; Stowe et al., 1998; Stromswold et al., 1996). Thompson et al. (2010) recently confirmed previous studies via fMRI tasks in healthy individuals, by demonstrating increased activation of the inferior and middle frontal gyri, the anterior middle and superior temporal gyri, the angular gyrus, and the insula, during processing object-cleft structures. It is further suggested that such syntactic processes modulate the flow of information from the inferior frontal gyrus to the posterior superior temporal cortex (den Ouden et al., 2012). However, alterations in activation patterns of temporal, frontal, and parietal areas are found to be associated also with semantic abilities (Meltzer et al., 2010). To overcome this issue, Moro et al. (2001) conducted a PET experiment which required detection of anomalies in written sentences consisting of pseudowords, thus neutralizing possible confounding effects of the semantic component. Their results confirmed previous findings supporting the involvement of Broca's area in syntactic and morphosyntactic processing.

Friederici and his colleagues have conducted several brain-imaging studies showing an association between highly demanding complex syntactic tasks and activation of frontal and temporal regions, that constitute a left-lateralized frontotemporal language network (Fiebach et al., 2005; Friederici, 2012, 2011; Friederici and Kotz, 2003; Obleser et al., 2011). On the basis of combined brain-imaging and lesion data, they propose a model for processing and integrating semantic and syntactic information in a temporal/spatial framework (Friederici, 2012, 2011; Friederici and Kotz, 2003). According to this model, linguistic stimuli undergo three distinct stages of processing: (1) acoustic/phonological analysis and processes of local structure building, (2) lexical–semantic and thematic processes, and (3) processes of syntactic revision and final integration. Each phase requires engagement of specific cortical areas interconnected by white matter tracts, within a proposed dynamic frontotemporal neural net, which comprises distinct brain regions specialized for analyzing semantic and syntactic information (Friederici et al., 2003).

Working Memory and Agrammatism

Recent studies argue about a language network consisting of two processing streams, one ventral and one dorsal (Hickok and Poeppel, 2004, 2007). It has been shown that the ventral stream connecting temporal and prefrontal areas via the extreme capsule fasciculus (originally described by Petrides and Pandya, 1988; see also Frey et al., 2008) mediates higher-level language comprehension (Saur et al., 2008). Since the time of Wernicke, the left posterior temporoparietal region is traditionally considered to be crucial for comprehension. Modern lesion studies have confirmed the findings of the German physician, pointing out that posterior lesions, including the superior and middle temporal gyrus, and the inferior parietal lobule, are related to comprehension impairment in aphasia (Kreisler et al., 2000; Dronkers et al., 2004; Leff et al., 2009). There are also brain-imaging studies on healthy individuals that support the above clinical data.

Temporal and parietal cortices are shown to be involved in lexical-semantic analysis of spoken words (Price, 2000; Salmelin, 2007). However, contextual comprehension requires an exchange of information between the aforementioned posterior areas and the prefrontal cortex. This exchange is served by the extreme capsule fasciculus (Saur et al., 2008). In sum, with regard to auditory sentence comprehension and syntactic processing, the reviewed studies described in the two former sections of the present paper reveal a dynamic, left-lateralized frontotemporal network, consisting of several cortical regions that possibly serve distinct subprocesses of syntactic comprehension and integration, at different stages (Friederici, 2012, 2011; Friederici et al., 2003; Friederici and Kotz, 2003)

Research on neural substrate of WM points to similar cortical and subcortical regions. With regard to the role of posterior and anterior cortices in the brain circuits responsible for verbal WM, lesion studies suggest a relation between posterior regions – such as the superior temporal gyrus – and WM (Beeson et al., 1993; Leff et al., 2009). However, a *meta*-analysis carried out by Wager and Smith (2003) on brain-imaging studies reports consistent activation of prefrontal areas during verbal WM tasks. Gerton et al. (2004) recently showed that healthy participants' performance of verbal WM tasks, such as digits forward and backward, elicits hemodynamic responses in both frontal and parietal regions. There are also studies demonstrating the involvement of the left hemisphere in nonverbal stimulus processing (Baldo and Dronkers, 2006; Kessels et al., 2002). Ricciardi et al. (2006) claim that a frontoparietal network supports such nonverbal information processing. Overall, it could be the case that both anterior and posterior cortical regions are engaged in verbal and nonverbal WM tasks, as if the central executive required both prefrontal and parietal regions (Collette and Van der Linden, 2002). It is already stated that an analogous network, including similar cortical and subcortical areas of the left hemisphere has been proposed for language (Hickok and Poeppel, 2004, 2007), and more specifically for syntactic processing (Friederici, 2012, 2011). Based on the above, it could be hypothesized that linguistic processes, such as syntactic comprehension, and executive functions, such as WM, may be parallel processes in terms of anatomy and physiology.

Imaging studies with healthy adults have shown that Broca's area hosts WM mechanisms that support processing of syntactically complex sentences. Moreover, when this region is lesioned subjects have difficulties processing such sentences. These findings have led to the idea that language deficits in agrammatism could be explained by appealing to WM (Grodzinsky, 2005). In fact, WM abilities in patients with aphasia have received a great deal of attention in the literature in the last decades. Caplan (2006) interprets the underlying cause of comprehension deficits in aphasics, in terms of impaired processing due to resource reduction. Newhart et al. (2012) have shown that damage to BA44 is associated with deficits with regard to phonological short-term memory, a construct that is considered to be one of the slave systems of WM. There are also several studies demonstrating that patients with aphasia often present with WM deficits in conjunction with their language problems (Burgio and Basso, 1997; Erickson et al., 1996; Kasselimis et al., 2013; Martin and Ayala, 2004; Martin and Saffran, 1997; Ronnberg et al., 1996; Shallice and Warrington, 1970). Moreover, it is argued that agrammatic aphasia is associated with impaired nonlinguistic cognitive sequencing, thus indicating that there are domain-general brain mechanisms subserving both language and sequential learning (Christiansen et al., 2010; Dominey et al., 2003). Brain-imaging data support this notion, by demonstrating engagement of Broca's area in both sentence comprehension and abstract sequence processing tasks (Hoen et al., 2006).

Some researchers have further suggested that WM deficits not only co-occur with language impairments but they may also contribute to them (Christensen and Wright, 2010; Friedmann and Gvion, 2003; Laures-Gore et al., 2010; Martin, 2008; Potagas et al., 2011; Wright et al., 2007). Taking into consideration the above data, we could hypothesize that agrammatic patients may suffer from a general WM deficit. Nevertheless, functional imaging data indicate that agrammatism cannot be easily attributed to a domain-general WM impairment. Recent PET and fMRI studies have shown that increased regional cerebral blood flow in Broca's area is associated with processing syntactically complex structures per se, rather than short-term or WM (Caplan et al., 2000; Christensen et al., 2012; Waters et al., 2003). It could be thus the case, that agrammatic patients suffer from a WM deficit related to specific linguistic phenomena, and Broca's area is associated with a domain-specific WM function (Fiebach et al., 2005; Hashimoto and Sakai, 2002; Stowe et al., 1998). It should be although noted that Broca's area has been also found to be associated with domain-independent processes, such as visuospatial modality syntax and hierarchical structures in several functional domains (Tettamanti et al., 2009; Tettamanti and Weniger, 2006). From an evolutionary perspective, it is highly plausible that language functions in general and syntactic abilities in particular emerged via natural selection, based on physiological preadaptations, such as WM cortical networks, consisting of interconnecting frontal, temporal, and parietal areas (Aboitiz, 1995; Aboitiz and García, 1997; Aboitiz et al., 2006; Lieberman, 1985, 1992).

Neuromarketing

Fabio Babiloni, University of Rome Sapienza, Rome, Italy

Abstract

Neuromarketing is an area of applied neuroscience devoted to the analysis of brain responses to advertising stimuli. It is generally perceived by the public as promoted by commercial interest in the use of neurophysiological tools able to track the main neurophysiological signals and consumer's behavior. However, in the scientific literature, a precise definition of the word 'neuromarketing' has been attempted. Neuromarketing is defined as "the application of neuroscientific methods to analyze and understand human behavior in relation to markets and marketing exchanges."

Introduction

In the economically developed countries, each day a person is reached on average by more than 100 commercial advertisements, through different media such as television, newspapers, radio, and the Internet. Such crowding of the advertising makes the job of marketers really difficult. In fact, they have to design and generate advertising messages able to compete with the others already running in order to capture our limited attention and memory resources. It has been pointed out how our body and the related sensory receptors are targeted by 10^7 information bits per second from the external world, while the average amount of such sensory perceptions retained in our memory is just 10 bits per second (Wilson, 2002).

The capability of a commercial advertisement to attract our attention is also a function of how often it reaches us each day through the different media, such as the television, radio, and the Internet. The greater the 'pressure' exerted by the ad, the easier we will remember it. However, due to the current economic crisis in the Western countries, the use of such 'pressure' leverage to increase memorability of an ad has become limited. For the same economic reasons, the interest in producing efficient and attractive advertisements has greatly increased.

Traditionally, investigations of the consumer's needs and desires have been performed through methodologies involving interviews with single consumers or small meetings with them, called focus groups. Focus groups and surveys are usually quite simple to run and not expensive. However, they are not particularly accurate in reporting consumer intention, due to the fact that people usually do not report clearly and completely what they think about a product (Griffin and Hauser, 1993). In addition, interview subjects are often unable to correctly report their feelings about the product under consideration (Green and Srinivasan, 1990).

In fact, it is recognized that often the verbal advertising pretesting is flawed by the respondents' cognitive processes activated during the interview, with the implicit memory and subject's feelings often inaccessible to the interviewer who uses traditional techniques (Zaltman, 2003). In addition, it has also been suggested that the interviewer with typical pretesting interviews has a great influence on what the respondent recalls and on the subjective experiencing of it (McDonald, 2003). In fact, the mismatch between the verbal report of consumers and their true internal feelings about the product has been thought responsible for the flop of about 70% of the new products launched on the world market.

Keeping all of these considerations in mind, researchers have attempted to investigate the signs of the brain activity correlated with an increase of attention, memory, or emotional engagement during the observation of commercials. Researchers within the neuroscience community promote the view that findings and methods from neuroscience complement and illuminate existing knowledge in consumer research in order to better understand consumer behavior (e.g., Ambler and Burne, 1999).

In this scenario, in this last decade the use of scientific results deriving from the neuroscience area related to the cerebral processes of attention, memorization, and emotion during activities related to the economic transactions has been explored by an increasing number of researchers. In particular, researchers have begun to investigate the brain areas involved in the generation of economic transactions by using different neuroimaging devices, such as functional magnetic resonance imaging (fMRI), the electroencephalogram (EEG), or the magnetoencephalogram (MEG) (see Ariely and Berns, 2010 for a review). Researchers have recently begun to investigate the neuronal mechanisms underlying a more specific form of economically relevant behavior, that is, consumer choices concerning the selection and consumption of certain products. In this approach, one is interested in the relationship between marketing stimuli to which individuals are exposed and the related brain responses.

From an economic and/or marketing perspective, the aim of such investigations is a better understanding of how consumer advertising of (established) brands affects brain systems. From a neuroscience perspective, the broad goal is a better understanding of both the neural mechanisms underlying the impact of affect and cognition on memory and the neural correlates of choice and decision-making.

While neuroscience is a general term to indicate the study of the nervous system that seeks to understand the biological basis of behavior, the application of neuroscience to *consumer psychology* has gained popularity over the past decade in academic research and business practice. In particular, an adopted definition of the *consumer neuroscience* area of research is that it is a discipline that adapts methods and theories from neuroscience in conjunction with different behavioral theories,

 http://dx.doi.org/10.1016/B978-0-08-097086-8.56029-2

models, and tested experimental designs from the area of consumer psychology. This is performed in order to develop a neuropsychologically sound theory to understand consumer behavior (Plassmann et al., 2012).

A final critical distinction is between *consumer neuroscience*, which refers to academic research performed in the area of consumer psychology and neuroscience, and the area related to the study of *neuromarketing*. The last area of study is generally perceived by the public as pushed forward by commercial interests in the use of neurophysiological tools able to track the main neurophysiologic signals and consumer's behavior to conduct company-specific market research.

However, in the scientific literature, a precise definition of neuromarketing has been attempted and proposed (Lee et al., 2007). In fact, the term 'neuromarketing' describes a field of study defined as "the application of neuroscientific methods to analyze and understand human behavior in relation to markets and marketing exchanges" (Lee et al., 2007). Such a definition has two main upshots: (1) it moves consideration of neuromarketing away from being solely the use of neuroimaging by commercial interests for their benefit; and (2) the scope of neuromarketing research is widened from solely consumer behavior to include many more avenues of interest, such as inter- and intra-organizational research, which are common in the marketing research literature. However, it must be stated that the term 'neuromarketing' is generally perceived as related to the study of the brain activity during its exposition to advertisements.

The incorporation of neuroimaging into the decision-making sciences has raised the interest of the marketing academia and professionals in this area of knowledge. It has been hoped that neuromarketing, with the associated neuroimaging technology, can aid marketers to generate a more efficient way to optimize the impact of advertisements on the human brain. In addition, it has also been thought that the use of neuroimaging measurements could return information about consumer preferences not immediately available through conventional methods (Ariely and Berns, 2010).

How Neuromarketing Methodologies Could Inform Marketing Processes

Nowadays, it has been clearly perceived that neuroscience imaging technology could be used to better understand the aspects of brain perception related to commercial advertisements. The use of such technology could be inserted in the cycle of the design, realization, launch, and support of a new product as described in **Figure 1**.

As described in **Figure 1**, neuroscience methodologies applied to the understanding of commercial advertising could have a role even before a single product could be realized. In fact, analysis of the consumer's brain responses due to the proposition of an 'idea' of a product could be performed. In this case, neuroimaging could be then employed to understand if consumers effectively agreed with the proposed idea or product concept, beyond their verbal opinion.

However, the most conventional use of neuroimaging in the analysis of marketing messages is generated in the area of the product cycle in which the product itself has been already realized and launched on the market. In this context, the analysis is of the impact on the consumer's brain of the particular advertising campaign supporting the product.

In this case, the dark box at the lower right of **Figure 1** describes the use of neuromarketing methodologies at the post-hoc evaluation of the advertising campaign produced. At this level, the corrections to be generated by the use of neuromarketing technologies could be applied not to the product itself but rather to the idea of the product conveyed to the consumers through the advertising messages. Neuroimaging studies could return information also useful for tailoring successive advertising campaigns related to the particular product launched.

Neurophysiologic Signals Used by Neuromarketing Methodologies

There are different kinds of neuroimaging technologies usually applied in the evaluation of the commercial products (or even ideas) in the neuromarketing area, and each specific technology involves the use of a particular neurophysiologic signal related to the brain activity.

The use of the variation of the hemodynamic blood flow in the brain during the observation of a particular ad is one of the most popular technologies employed in neuromarketing. In particular, fMRI has been largely validated in neuroscience during the last 20 years as a methodology able to reveal the activity of brain areas with a remarkable spatial resolution (on the order of mm) and an acceptable time resolution (seconds). Several companies offer neuromarketing services based on fMRI neuroimaging devices for the analysis of commercial advertising. The use of fMRI in this area of applied science is partially limited by the relatively high cost of the fMRI analysis per subject, in particular when compared to other neuroimaging technologies such as the EEG. However, the use of fMRI allows the analysis of the activity of particular subcortical structures known to be involved in the appreciation and avoidance of the presented stimuli, such as the nucleus accumbens. Such capability cannot be achieved by using EEG or MEG techniques. A partial limitation of fMRI for use in a marketing context is its limited temporal resolution (on the order of seconds), which represents an obstacle for the use of such a technique for the time-varying evaluation of commercial TV spots.

The measurement of electromagnetic activity related to the brain activity through an EEG or an MEG is another popular approach in the neuromarketing area (Ioannides et al., 2000; Vecchiato et al., 2010). The main limitations of EEG or MEG neuroimaging technologies are related to the moderate spatial resolution achievable (cm) and to the relative difficulty for the detection of the cerebral activity originating at the subcortical structures, such as the nucleus accumbens or the amygdala. However, a great advantage of the EEG and MEG technologies when compared to fMRI is related to their high temporal resolution, which is on the order of ms. Such temporal resolution is more than sufficient to track the time-varying changes of cortical brain activity during the observation of a TV commercial, making the EEG or MEG a good choice for the evaluation of cerebral impact of a TV

Figure 1 A possible scheme for the design and the launch of a new product on the market. The dark box indicates the possible use of neuromarketing methodologies, able to generate insights in the evaluation of the new concepts to be implemented in a product. Such use could take place in an early phase before the generation of the product itself (upper dark box) or in a post-hoc evaluation of the already-launched advertising campaign (the dark box at the bottom right of the figure).

ad. It is worth noting that MEG devices are relatively scarce in the world (due to their cost), while EEG devices are relatively cheap when compared to fMRI or MEG technologies. Such considerations explain why the use of EEG technology is largely adopted by many neuromarketing companies for the evaluation of marketing relevant stimuli.

There are other devices and technologies that could be used in the evaluation of the consumer's cerebral activity during the evaluation of marketing messages. These devices usually measure the indirect signs of the brain activity, mediated by the autonomous nervous system or through the facial muscles or eye movements.

Eye-tracking devices are usually employed in marketing research by tracking eye movements through different sensors such as glasses or even a camera placed on a monitor's screen. Some eye-tracking devices are also able to return information on the diameter of the pupil, which is thought to be linked to the general arousal level of the subject. Extensively used in neuromarketing practice, eye-tracking devices return information about the gaze direction and are used to evaluate the main attractive points of a static marketing message, such as an advertisement on a wall, rather than a TV commercial.

The time-varying signals provided by cutaneous impedance, usually measured at the finger level, is known as electrodermal activity (EDA; Critchley, 2002). EDA signals the variation of the autonomous sympathetic system, with a time resolution of less than 1 s. The kind of information returned by EDA measurements is related to the fluctuation of the arousal level, which is a valuable source of information about comfort or discomfort of the person at a point of sale or when watching a TV commercial. EDA evaluation is offered by several companies that link such arousal variation (Critchley, 2002) with the emotional involvement generated by the advertising.

Another signal employed in neuromarketing is the heart rate, that is, the instantaneous frequency of the heartbeats. Such a variable is again linked with the general arousal state of the person during the observation of advertising. Heartbeat is often collected in conjunction with the level of EDA responses, for a full characterization of the time evolution of the consumer's autonomic system in correlation with the presentation of the advertising.

In particular, by monitoring autonomic activity using devices able to record the variation of skin conductivity and heart rate, it is possible to assess the 'internal' emotional state of the subject. In fact, the EDA is actually viewed as a sensitive and convenient measure of indexing changes in sympathetic arousal associated with emotion, cognition, and attention (Critchley, 2002). Studies using functional imaging techniques have related the generation and maintenance of EDA level to specific brain areas. These specific regions are the ventromedial prefrontal cortex, orbitofrontal cortex, left primary motor cortex, and the anterior and posterior cingulate, which have been shown to be associated with emotional and motivational behaviors (Critchley, 2002). Such findings indicating the close association of peripheral and central measures of arousal reemphasize the close connections between EDA, arousal, attention, cognition, and emotion. In addition, the link between heart rate or heart rate variability and the sympatho/vagal balance has already been suggested (Malik, 1998).

Main Cerebral Structures Involved in Advertising and Brand Evaluation

It has been emphasized how a positive or negative emotional processing of advertising is an important factor for the formation of stable memory traces (Kato et al., 2009). Hence, it became relevant to infer the emotional engagement of the subject during the observation of an advertising message. In fact, indirect signs of emotional processing could be gathered by picking variations of the activity of the anatomical structures linked to such processing activity in humans. Indirect signs of emotional activity could be extracted by using galvanic skin response measurements, linked to the modulation of activity of the sweat glands on the hands or by using the heart rate measurements (Baumgartner et al., 2008). Direct signs of emotional activity could be obtained by gathering the variations of the cerebral activity on the prefrontal and frontal cortices (PFC and FC, respectively) by EEG (Davidson and Irwin, 1999).

In fact, the PFC region is structurally and functionally heterogeneous but its role in emotion is well recognized (Davidson, 2002). EEG spectral power studies indicate that the anterior cerebral hemispheres are differentially lateralized for approach and withdrawal motivational tendencies and emotional appreciation (Davidson and Irwin, 1999; Davidson, 2000, 2004). Specifically, several EEG findings suggest that the left PFC is an important brain area in a widespread circuit that mediates appetitive approach, while the right PFC appears to form a major component of a neural circuit that instantiates defensive withdrawal (Davidson, 2000, 2004).

It has also been proposed that the use of the unbalancing of the EEG spectral activity over the left and right prefrontal area in humans could be a reliable indicator of the prevalence of the 'approach' system when compared to the 'withdraw' one during the observation of different stimuli (Silberstein and Nield, 2012).

With such index, it has become possible to judge how much one likes a commercial during its temporal development, in order to determine the part of it that caused major appreciation from the observer and the part that did not.

However, the major part of the information about the brain structures involved in the appreciation of advertising in the literature has been obtained by the use of hemodynamic signals. In particular, an important body of research in advertising has been performed with the use of fMRI for the analysis of the 'brand' concept and for the localization of brain areas that respond to brands presented in different experimental conditions. Such research will now be briefly discussed.

It has been reported in a study by Deppe et al. (2005a) that the ventromedial prefrontal cortex (vmPFC) showed greater activity during the observation of a preferred brand as contrasted to the second or lower ranked brands in a healthy population. Of note, in a study by Koenigs and Tranel (2008), patients with damage in the same cortical structure (vmPFC) were not biased by brand information during blind versus open tasting of carbonated drinks (Coke and Pepsi). Taken together, such studies suggest an involvement of the vmPFC in favorite brand appreciation. However, the vmPFC is not the only brain structure that is active during such brand observation and appreciation. In fact, an fMRI study reports that observation of familiar brands by subjects activates their middle frontal gyrus when compared to the observation of unfamiliar brands (Schaefer et al., 2006). In addition, different studies suggested that brain activity at the anterior cingulate cortex could predict whether a person is biased by the brand name of a newspaper while evaluating the credibility of a headline or the attractiveness of print advertisements (Deppe et al., 2005b, 2007). Consistent activity was also observed in the ventral striatum during the imagined consumption of a product of preferred brands (Schaefer and Rotte, 2007), or during the observation of brands to which subjects are 'loyal' when compared to the observation of brands to which the subjects were 'unloyal' (Plassmann et al., 2007). In addition, the network of the cerebral areas active during the brand judgments are different than those elicited in the case of judgments related to humans traits (Yoon et al., 2006).

Imaging by fMRI has also been used to study how brand information could alter brand evaluation during product consumption. In a famous study, the stated preferences for Coke versus Pepsi did not correlate with the revealed preferences in blind tasting (McClure et al., 2004). However, revealed preferences correlated with the brain activity changes in the vmPFC and in the medial orbitofrontal cortex. In addition, awareness by the subjects that they were drinking Coke generated activity changes in memory and association areas (hippocampus, dorsolateral PFC), while no such difference could be found in the case of Pepsi (McClure et al., 2004).

In conclusion, the use of neuroscience information for the evaluation of commercial ads or brands has become popular nowadays and represents one of the first and most evident applications of neuroscience into an industrial area not related to healthcare. Although several difficulties are present in extending the above-mentioned neuroscience findings into practical and marketing-relevant information, namely due to the reverse inference problem, there is no doubt that the possibility of mapping brain activity related to the evaluation of marketing messages will be followed with a lot of attention by the marketing industry in the years to come.

Abstract

Neurons are the building blocks of the brain. This article reviews the basic components and biophysical mechanisms that underlie nerve cell function, including a discussion of ion channels, the membrane potential, electrical signaling, synaptic function, and synaptic integration. The implications of these electrophysiological phenomena are then examined in relation to theories of information processing in single neurons.

Introduction and Scope

At the beginning of the twenty-first century, neural tissue remains arguably the most powerful substrate for information processing in existence. Unfortunately, the principles underlying brain function are still known only in rough outline. To unlock the many secrets of the brain and to help explain the panoply of neural functions ranging from simple motor reflexes to conscious thought and action, neuroscientists have amassed an extensive body of experimental data bearing on the properties of nerve cells (neurons) and their interconnections (synapses), which together form the building blocks of neural tissue. At the same time, the functional significance of the neurobiological data has been explored in computer modeling studies, which have often been used to test hypotheses inaccessible to direct experimental approaches. This article summarizes what is known about the intracellular physiology of individual nerve cells and interprets these data in relation to the information processing functions of single neurons. For comprehensive treatments of many of these same issues, see Stuart et al. (1999) and Koch (1999).

Given the morphological and functional diversity of neurons across the invertebrate and vertebrate phyla, the present article is focused on the principal neuron types of the vertebrate central nervous system (CNS), though much of what is discussed applies to neurons in general. This focus is justified, first, by the fact that neurons of the vertebrate CNS have been among the most frequent objects of correlated physiological, behavioral, and modeling studies, and second, by the fact that these cells are those which most directly underlie the cognitive and behavioral phenomena with which this volume is concerned.

Basic Construction of a Neuron

The typical neuron of the vertebrate CNS is composed of (1) a cell body, or soma, which contains the nucleus and other molecular machinery present in any living cell, (2) the dendritic tree, which emanates from the cell body and acts as the main input-receiving surface of the neuron, (3) the axon, which carries output signals generated by the neuron over long distances to other neurons, and (4) a large number of synapses, the specialized sites where axons make contacts with the dendrites and cell bodies of other neurons for subsequent processing (**Figure 1**).

The axon, a thin fiber emanating from the cell body, is the cell's final common output used to convey messages to other

Figure 1 (Left) Pyramidal cell from rat parietal cortex. Dendrites protruding from the cell body (dark pyramidal shape) have tiny protrusions (spines) covering the dendritic branches are the sites of most excitatory synapses. One pyramidal cell may contain tens of thousands of spines. Inhibitory synapses are less numerous, occur primarily on dendritic shafts and are concentrated near the cell body. Axon is the smooth protrusion from the bottom of the cell body. (Right). Model neuron with *m* identical branches containing *k* synapses each.

neurons. The axon carries trains of 'action potentials' (APs), all-or-none voltage spikes 60–100 mV in height and 1–2 ms in duration, which propagate undecremented along the length of the axon at speeds up to 100 m s^{-1}. The single axon of a neuron, which may travel over distances ranging from millimeters to meters depending on the neuron and which may branch profusely at one or more sites along its run, gives rise to many thousands of synaptic terminals impinging on the dendrites and cells bodies of hundreds to thousands of other neurons. Neurons can fire APs at rates up to 1000 impulses per second, though the maximum firing rate for most neurons in the CNS lies in the range of 100–200 Hz. APs are triggered when the membrane potential at the site of spike initiation reaches a firing threshold. In a typical neuron, this threshold is around −50 mV, that is, about 20 mV more positive than the cell's resting potential of −70 mV. While APs are thought to be triggered in the axon near the cell body, the electric currents that flow there represent the combined influences of many widely scattered synaptic inputs acting on the soma/dendritic membrane.

The dendritic tree is the main input-receiving domain of the neuron, generally accounting for more than 95% of the cell's total surface area, and receiving many thousands of synaptic inputs from other cells. With a few notable exceptions, the dendrites of CNS neurons are purely input structures (Shepherd, 1998). A synaptic input to a dendrite can be categorized roughly as either 'excitatory' or 'inhibitory,' meaning that when the synapse is activated, the membrane on the 'postsynaptic,' that is, dendritic side of the synaptic junction is driven transiently to a more positive (excitatory) or more negative (inhibitory) potential. Most of the contacts on a dendritic tree are excitatory (80–90%); inhibitory contacts can occur anywhere, but tend to be concentrated on or around the cell body. A synaptically evoked change in membrane potential can have a time course ranging from one to hundreds of milliseconds, depending on the type of synapse. In addition, synaptic inputs can trigger 'active' dendritic responses, including complex spike-like events involving both fast and slow components (e.g., Kamondi et al., 1998; Golding et al., 1999). Thus, the rules that govern how excitatory and inhibitory synaptic inputs are combined and transformed within the dendritic tree to produce outbound APs can be quite complex. This process commonly is referred to as synaptic or dendritic 'integration,' and is the focus of the remainder of this article.

The Membrane Potential

To understand how synaptic and other electrical events combine to generate APs, it is important to understand the basic electrical properties of 'neurites' (axons and dendrites).

The resting membrane potential of a neuron, as for any living cell, is established by molecular pumps, which actively maintain concentration gradients of sodium (Na^+) and potassium (K^+) ions across the cell membrane. Relative to the extracellular fluid, the inside of the cell contains a high concentration of K^+ ions and a low concentration of Na^+ ions. The constant pressure on these electrically charged ions to flow across the membrane down their respective concentration gradients (Na^+ in, K^+ out), is analogous to the pressure electrons feel that propels them from the negative to the positive terminal of a battery given a suitable path for current. The electrical pressure on each of these ions can thus be represented by a battery, whose voltage conveys the magnitude and direction of the ion's concentration gradient; the fact that the Na^+ and K^+ batteries point in opposite directions will turn out to be critical for electrical signaling.

Since the membrane–lipid bilayer is itself impervious to ions, currents can only flow through 'ion channels,' specially designed pores in the membrane formed by large, membrane-spanning protein complexes. Ion channels are generally quite selective as to which ions may flow through them, giving rise to the nomenclature 'sodium channels,' 'potassium channels,' and so on. Furthermore, certain ion channels are tonically open, while others can open and close under the control of various signals. For example, some channels open and close in response to changes in the membrane potential, such as occurs in the production of APs, others in response to chemical signals, such as occurs in the production of synaptic potentials.

The resting membrane potential of a neuron is a weighted average of ionic battery values, where the weight given to each ion's battery is determined by the membrane's total electrical conductance (g_I) to ion I through all open channels

$$V_m = \frac{g_{Na}E_{Na} + g_K E_K + \cdots}{g_{Na} + g_K + \cdots} \quad [1]$$

The usual resting potential around $V_m = -70$ mV is dominated by a K^+ conductance, whose associated battery value is $E_K = -90$ mV. An additional small resting Na^+ conductance, whose associated battery value $E_{Na} = +60$ mV or higher, pulls the resting potential to some 20 mV in the positive direction.

Electrical Signaling Results from Conductance Changes

Electrical signaling in a neuron is caused by transient changes in the conductance of various ion channels, which cause transient fluctuations in the membrane potential about its resting value. At every moment in time, the membrane potential moves toward the equilibrium value given by eqn [1] – not instantaneously – but at a rate limited by the need to charge or discharge the membrane capacitance. The classical signal generated by a neuron is the AP. When a synaptic or other injected current drives the membrane potential to a threshold of approximately −50 mV, a population of voltage-dependent Na^+ channels, normally closed at rest, opens abruptly to a large conductance value resulting in a large influx of current. As predicted by eqn [1], this leads to a rapid voltage upswing as the membrane potential spikes toward the Na^+ battery potential of +60 mV. Within a fraction of a millisecond, however, the Na^+ channels begin to close, or 'inactivate,' of their own accord. At the same time, voltage-dependent K^+ channels sense the voltage upswing on the leading edge of the AP and open to produce a large outward current. The combined effects of Na^+ channels closing and K^+ channels opening result in an abrupt downswing in the membrane potential to terminate the AP.

Active electrical responses of the neuronal membrane have historically been most closely associated with the long-range signal transmission function of the axon. It is now apparent, however, that the dendrites of many neuron types contain voltage-dependent channels capable of generating spikes, which are independent of the cell body (Amitai et al., 1993; Golding and Spruston, 1998; Kamondi et al., 1998). Unlike the stereotyped all-or-none form of the classical AP, however, synaptically evoked dendritic spikes are of variable magnitude and can consist of complex superimpositions of fast and slow events. As discussed below, this highly nonlinear electrical behavior of dendritic origin is likely to profoundly influence the integrative properties of nerve cells.

Synaptic Inputs

Synaptic potentials, the principal input signals to which a neuron responds, likewise, are evoked by changes in the conductance of ion channels in the postsynaptic membrane. In this case, the conductance changes are triggered by the binding of neurotransmitter molecules to receptors exposed on the extracellular surface of the membrane. The normal sequence of events in synaptic transmission is as follows. An AP invades the presynaptic axon terminal. The voltage upswing in the presynaptic terminal opens voltage-dependent calcium (Ca^{++}) channels leading to a rapid influx of Ca^{++} ions. A small number of vesicles (usually zero or one) containing neurotransmitters fuse with the presynaptic membrane at specialized release sites and disgorge their contents into the synaptic cleft. The neurotransmitter (e.g., glutamate or GABA) diffuses the several nanometers across the synaptic cleft in a fraction of a millisecond and binds with receptors on the postsynaptic membrane. Upon binding, the receptor–channel complex undergoes a conformational change, causing the channel to open. Alternatively, in the case of 'second messenger' transmission, the protein to which the neurotransmitter binds is not the channel itself, but instead triggers a cascade of biochemical reactions inside the postsynaptic cell, which lead indirectly to the opening or closing of ion channels. In either case, the resulting conductance change(s) cause the membrane potential in the postsynaptic compartment to fluctuate toward the characteristic battery value for that synapse, often called the synaptic 'reversal potential.' The reversal potential at an AMPA- or NMDA-type excitatory synapse is typically 0 mV, 70 mV more positive than the resting potential. This value results from an approximately equal conductance to Na^+ and K^+ ions. A synapse with a reversal potential around 0 mV is termed 'excitatory,' since under normal operating conditions with a negatively polarized membrane potential, activation of the synapse drives the membrane transiently to more positive potentials (i.e., toward 0 mV). This 'depolarization' increases the likelihood (or rate) of outbound AP production in the postsynaptic cell. Conversely, the reversal potential is −65 mV for $GABA_A$-type inhibitory synapses that conduct chloride ions and −90 mV for $GABA_B$-type inhibitory synapses that conduct K^+ ions. In either case, the activation of the synapse opposes synaptic excitation by transiently pulling the membrane potential to more negative values, thus reducing the likelihood (or rate) of AP generation.

Synaptic Integration

To this point, we have seen how transmitter-dependent and voltage-dependent gating of ion channels can produce the fluctuations in membrane potential that underlie both synaptic responses and APs. But what are the rules governing synaptic integration?

The simplest 'linear' model of dendritic integration holds that the neuron sums its excitatory and inhibitory influences across the dendritic arbor, followed by a global thresholding nonlinearity at the cell body (McCullough and Pitts, 1943; Rosenblatt, 1962; Rumelhart and McClelland, 1986). Despite its simplicity (**Figure 1**), this formulation has influenced thinking about neuronal function in both the experimental and computational communities for many years. Extensions to this idea that explicitly include the 'passive cable' properties of the neuron – accounting for attenuation of signals with time and distance (Rall, 1964; Koch et al., 1982; Agmon-Snir and Segev, 1993) – have also been highly influential and have led to a variety of productive interchanges between theory and experiment (Rall et al., 1992).

From the perspective of currently available neurophysiological data, however, much of it derived from direct intradendritic recordings, synaptic integration is likely to be more complex than can be captured by linear or passive models of dendritic function (Segev and Rall, 1998; Mel, 1999). The question is complicated for three reasons, principally relating to uncertainties as to how or to what extent synaptic inputs interact with each other through shared voltage or chemical signals within the dendrites.

First, the spatiotemporal patterns of synaptic activation driving neurons in the CNS *in vivo* are not well known; so that current best guesses as to the electrical and chemical environments in which synapses normally operate remain largely rooted in conjecture.

Second, synaptic inputs may trigger secondary events in the dendrites mediated by voltage-dependent NMDA, Na^+, K^+, and Ca^{++} channels, which could influence significantly how excitatory and inhibitory synaptic inputs are combined to produce overall neuronal responses. Synaptically evoked dendritic spikes have been observed *in vitro* (Golding and Spruston, 1998; Schiller et al., 2000) and *in vivo* (Kamondi et al., 1998), though it is not yet known whether such events occur commonly in awake, behaving animals, and if so whether they are localized to one or many dendritic branches, and so on. In addition, the spatial distributions of these channels on the cell surface, their kinetic properties, their dependence on voltage and other modulatory factors, and their efficacies under normal *in vivo* operating conditions are not sufficiently well known to make firm predictions regarding the contributions of these channels to the integrative processes of the cell.

Third, cable theory (Jack et al., 1975; Koch, 1999) informs us that the dendritic morphology of a typical CNS neuron – typically consisting of many thin-branch subtrees radiating

outward from the cell body and/or main dendritic trunks – is ideally suited to isolate voltage signals within specific subregions of the dendritic arbor. Thus, the electrical coupling between a thin branch and a main trunk (or soma) is expected to produce a significant attenuation of distally generated voltage signals when measured at the trunk, with the most profound suppression of signal transmission reserved for rapid voltage transients associated with fast synaptic potentials or dendritic spikes. Thus, if thin branches, which receive the vast bulk of the excitatory input in most neurons, routinely generate fast spike-like events in response to synaptic excitation, the cable structure of these cells appears designed to ensure that distally generated spikes are seen only in strongly attenuated form in other parts of the cell. Clearly, this type of functional compartmentalization could complicate the issue of synaptic integration, since the overall response of the cell would depend on whether synaptic inputs were delivered to the same or different dendrites, and whether dendritic spikes were generated or not.

Synaptic Plasticity

When a neuron fires an AP, it is propagated from the axon hillock down the axon. But there is often also a back-propagated action potential (bAP) going from the axon hillock back through the dendrites. The bAP produces a feedback signal that provides the entire cell body with information about the output state of the neuron (Magee and Johnston, 2005). The bAPs appear to act to enhance synaptic plasticity by tying together the timing of the Ca^{++} influx of the synaptic input and AP output, provided that they occur nearly coincidently within a tight window of <50 ms. This enables the production of a larger Ca^{++} signal than the input would produce alone and provides a candidate mechanism for aspects of synaptic plasticity. Such a mechanism lends more support to the view that dendrites are key integrative units playing computational roles such as in learning and memory, the mediation of attention or motor output (Behabadi and Mel, 2014; Shah et al., 2010).

Computational Implications

In spite of many uncertainties, currently available experimental data, combined with insights gained from theoretical and modeling studies, seem to support the hypothesis that dendritic trees are compartmentalized functionally and could consist of a moderately large number of, for example, up to 100, independent integrative 'subunits.' The idea that dendritic trees are compartmentalized functionally has been discussed in a variety of forms over the years (Koch et al., 1982; Shepherd et al., 1985; Rall and Segev, 1987; Mel, 1992a,b, 1993; Mel et al., 1998; Archie and Mel, 2000; Poirazi and Mel, 2001). In the continued absence of empirical evidence sufficient to confirm or deny this 'nonlinear subunit' hypothesis, several recent modeling studies have provided support for one simple version of the idea. According to this model, each dendritic subunit, corresponding to a single branch or small thin-branch subtree, acts as a separately thresholded neuron-like summing unit, and all the subunit responses are summed in the main trunks and the cell body to produce the cell's final output (**Figure 1**). This formulation ignores differences in the locations of synapses within a subunit, as justified by theoretical considerations and biophysical modeling studies, indicating that voltage signals are communicated far more effectively within a dendritic branch than between branches – especially for branches separated by a main trunk or the cell body. In mathematical terms, the neuron's overall output y is given by a sum of m independently thresholded subunit responses. Each subunit response is given by a weighted sum of k inputs followed by a fixed subunit nonlinearity, g, which is typically modeled as a sigmoid or power function

$$y = \sum_{j-1}^{m} g\left(\sum_{i-1}^{k} w_{ij}x_{ij}\right) \qquad [2]$$

This simple formula, which is similar to the expression describing a conventional two-layer neural network (Bishop, 1995), was found to predict the time-averaged firing rates produced by a biophysically detailed compartmental model of a pyramidal cell, a model which included passive membrane properties, a spatially extended dendritic morphology, synapses with realistic conductance models, and voltage-dependent ion channels in the dendrites (Archie and Mel, 2000).

From a functional perspective, it is interesting to note that the sum-of-thresholded-subunits model captures the underlying structure of a variety of classical and extraclassical receptive field properties found in cortical neurons, suggesting that dendritic subunits could contribute in important ways to the many quotidian signal-processing functions of cortical tissue (Mel, 1999). In a different vein, a recent modeling study has shown that subunit-containing neurons as described in eqn [2] could increase the trainable storage capacity of neural tissue by orders of magnitude (Poirazi and Mel, 2001).

While it is clear that many questions remain to be answered regarding the information processing functions of single neurons, one may be confident that with the steady advance of experimental methods available to study neuronal function at the required level of detail, coupled with the enormous flexibility of hypothesis testing provided by the computer modeling enterprise, the many fascinating secrets of neural information processing will gradually yield in the coming years.

Abstract

The development of language from neurophysiological aspects using event-related potentials (ERPs) are described. Mismatch negativities (MMN), P300, and N400 are the classification of ERPs based on the time course. MMN and P300 represent, respectively, passive perception and active discernment of the difference in several kinds of stimuli, especially pairs of tone bursts (TB) and verbal sounds (VS). N400 is related to the semantic processing of the language. The author will describe about developmental changes of MMN, P300, and N400 potentials as the neurophysiological markers in language development, which are highly related to the recognition of VS and the semantic meaning of the words.

Introduction

Language is the visible or invisible symbol of internal process of constructing idea, learning anything, and processing any perceptive or emotional stimulus. It is also an important medium for communicating with others. Markers of language development have historically been studied mainly from the viewpoint of developmental milestones by many psychologists, speech pathologists, and developmental pediatricians. Expressive and receptive abilities are usually the target of explorations of language evaluation in children, along with the development of intelligence, vision, hearing, social interactions, and so on. Especially, child's age at the utterance of the first word and sentence, the increment curve of vocabulary, and the capability of obeying oral commands are often the developmental markers of expressive or receptive language. Those topics are discussed precisely in other chapters.

Therefore, in this article, the development of language from neurophysiological aspects using event-related potentials (ERPs) will be described. Electroencephalographic procedures including evoked potentials (EPs) and ERPs can reveal the temporal resolution of the cognitive information processing. This kind of quantitative and objective measures of evaluation in language development will surely add some useful information about our understanding of the developing brain.

ERPs are recorded as computer processed electroencephalographic activities elicited by certain internal and external cognitive affairs. This cognition includes perception, attention, discrimination, judgment, expectation, and so on. ERPs are classified by time course, the sensory modalities, and passive/active attitude of subjects. Mismatch negativities (MMN), P300, and N400 are the classification based on time course. MMN usually appears around 200 ms after the stimuli presentation and represents passive perception of the difference in several kinds of stimuli. P300 is recorded about 300–400 ms after the beginning of tasks and represents active discernment of the same kinds of stimuli described above. N400 is elicited about 400–600 ms and is related to the semantic processing of the language. The origin of each ERP has been explored extensively and is also a subject of research. ERPs are applied to the typically developed subjects as well as patients with various neurological/psychiatric diseases and with developmental delay to reveal their cognitive function. In this article, the author will describe about developmental changes of MMN, P300, and N400 potentials, which are highly related to the recognition of verbal sounds (VS) and the semantic meaning of the words.

MMN

MMN was first reported by Naatanen in 1987. MMN is generated by automatic response to any change in outer sensory stimulation exceeding a certain limit of corresponding roughly to the behavioral discrimination threshold. MMN is a negative displacement at the fronto-central electrodes relative to reference electrodes in the difference wave elicited as the subtraction wave of frequent (standard) from rare (deviant) stimuli. Research in MMN has mainly been focused in the response elicited by auditory stimuli. Most studies have been done using tone bursts (TB) at the frequencies of 1000 and 1200 Hz with 60 to 70 dBHL in intensity. However, the difference wave induced by visual stimuli also disclosed the presence of MMN in a similar pattern (Horimoto et al., 2002).

Language development is highly influenced by the hearing acuity and understanding of spoken language. Consequently, researches using auditory stimuli are very important. The first gate of speech development is to differentiate VS unconsciously then consciously. Development of phonological perception has shown that even infants at the age of 1 month can differentiate (ba) (pa) sounds, as revealed by habituation methods (Eimas et al., 1971). Moreover, (da) (ta) sounds in infants (Novak et al., 1989) could be differentiated by auditory cortical response or (l) (y) sounds (Cheour-Luthtanen et al., 1995) in neonates of 1–4 days old could elicit mismatch negativity.

As to MMN to TB, Fuchigami (Fuchigami et al., 1995) examined the results of ERP of ignoring condition in 108 subjects aged 1 to 21 years old. They made clear that their latency was decreased as the subjects grew older. In the same year, Woods (1992) reported the middle aged and elderly adults showed the MMN using TB with the latency of 150–210 ms with reduced amplitude in the elderly subjects.

Kraus et al. (1992) reported that the MMN induced by speech sounds, (ba) and (da) in children aged 7 to 11 years old

 http://dx.doi.org/10.1016/B978-0-08-097086-8.23135-8

in 1992. This potential was also confirmed by magnetoencephalography in 11 children aged 5–7 years old. MMN induced by TB stimuli and VS stimuli TB and VS develops independently but similarly (Pihko et al., 2005). Moreover, the latency of MMN to VS is longer than that of to TB. This suggests that the VS has more complex components than TB and need to be trained to acquire and recognize. We can only speculate the difficulty in distinguishing complex combination of words in the developing brain.

P300

P300 was first reported by Sutton et al. (1965) and has been widely applied to the patients with developmental disorders (Niwa et al., 1983; Courchesne et al., 1984; Kileny et al., 1997) and neurological/psychiatric diseases.

P300 is a response to represent the internal process of stimulus perception, discrimination, and judgment. Subjects must differentiate two or more different kinds of stimuli presented as the oddball paradigm and must choose the target stimuli. P300 appears clearly to the target stimuli after about 300 ms of stimulus presentation with centro-parietal dominancy. To make the best combination of the stimuli is very important to evaluate the ability of discrimination of the target stimulus.

Historically, most studies concerning the development of P300 were performed using nonverbal stimuli such as TB of 1000 and 2000 Hz, and rarely using verbal stimuli (Gordin et al., 1978; Polish et al., 1985; Martin et al., 1988). Concerning the cognitive development of the primary active discrimination of VS, P300 induced by TB stimuli should be compared with that of VS. Of course, to explore the cognition higher than that of verbal sound level, usage of words and sentences as the tasks could be ideal. However, P300 cannot be elicited by these tasks with such a long duration like sentences. As to the P300 induces by VS has been reported that the latency to VS was longer than to TB in adults and in children (Groenen et al., 2001; Hatori et al., 2004). This finding suggested that longer time was necessary to process multiple and complex frequency sounds (VS) rather than a single frequency sound (TB). Previous reports on the developmental change of P300 elicited by TB showed the inclination curve was calculated as the linear function (Gordin et al., 1978; Polish et al., 1985; Pearce et al., 1989). These approximations were elicited by the limited results in studies of children.

In 2004, a report compared results for P300 induced by TB and VS as an oddball paradigm in the same persons of a variety of age was published (Hatori et al., 2004; **Figure 1**; **Figure 2**). Their subjects, all right-hand-dominant native Japanese speakers, were divided into two groups; which one group consisted of 19 adults (24.3 ± 3.0 years old) and the other consisted of 13 children (10.0 ± 2.4 years old). Auditory oddball TB tasks were 1 kHz and 750 Hz in frequency, while VS tasks were [ae] and [a]. [ae] sound was the target and [a] sound was nontarget. [ae] is not present in Japanese pronunciation but [a] is present in Japanese pronunciation. None of the subjects made any mistakes in pressing key. Especially, the latency of P300 induced by VS was longer than that induced by TB in both groups. The dominant area of P300 was Pz in both children and adults (**Figure 3**). The peak latency of P300 (Y ms) and age (X years old) were approximated as $Y = 0.5071X^2 - 21.056X + 516.2$ for TB and $Y = 0.5683X^2 - 26.744X + 663.32$ for VS (**Figure 4**). Therefore, the age with the shortest latency of P300 to TB was 20.8 years old and was 23.6 years old to VS. Compared to TB, VS had a stronger inclination of the diminution speed of latency at 10 years old, and the latency of VS was longer than that of TB. This shows the learning process of differentiation of VS from TB progresses steadily and VS processing speed is faster than that of TB.

Thus the analysis of successive age subjects made clear the age of the shortest latency to TB and VS. Namely, the difference

Figure 1 Grand average wave of children ($n = 13$), ▽: N1, ▼: N2, ▲: P300. Cited and modified from Hatori, T., Inagaki, M., Shirane, S., Kaga M., 2004. was 3 years old. However, approximation curve revealed they were independent and never crossed over. Development of P300 latency reflects qualitatively different cognitive process. These results provide developmental process of perception and discrimination of TB and VS.

N400

N400 was first reported by Kutas and Hillyard (1980) and have been investigated for years by many researchers (Monetta, 2003; Kutas et al., 1994; Jouttonen et al., 1996; Yano et al., 1999; Yano and Kaga, 2000; Coch et al., 2002; Bonte and Blomert, 2004). N400 of ERP reflects linguistic process and has been studied with a semantic priming paradigm with lexical decision tasks (Holcomb, 1993; Kutas, 1993). For example, subjects were asked to judge whether a target word was a word or nonword, whether a presented sentence made sense or not, or whether a presented prime word was related to the target word or not. Many studies have been done applying to typical developed adults to solve these tasks in linguistics. So, it is often difficult to apply these tasks to children.

Despite many investigations on N400, studies using the same tasks in the different modality to the same subjects have

Figure 4 Developmental change of P300. The relation of ages (X years old) and P300 peak latency (Y ms) showed the below function. ○: tone bursts $Y = 0.5071X^2 - 21.056X + 516.2$ ($p < .001$, $r^2 = 0.2736$), ●: verbal sounds $Y = 0.5683X^2 - 26.744X + 663.32$ ($p < .001$, $r^2 = 0.6053$). Cited and modified from Hatori, T., Inagaki, M., Shirane, S., Kaga M., 2004. Clinical neurophysiological study of verbal and non verbal sound perception: normal development of P300 event related potential to different sound stimuli (in Japanese). No to Hattatsu 36, 232–239.

not been done. (Oana et al., 2006) made a new task called the semantic category decision task. This task is rather simple, so children who can read only kana letters (Japanese phonetic letters) can accomplish it. They provided three types of tasks; namely auditory, visual, and auditory–visual (bimodal), with which examined the developmental change of N400.

Their subjects were 38 typical developed children and adults aged 6–30 years old who were divided into three groups, 18 younger age group (6–9 years of age, mean standard deviation was 7.3 ± 1.1), 10 elder age group (10–14 years old, 11.6 ± 1.3), and 10 adults (22–30 years old, 26.6 ± 2.7).

In the semantic category decision task, a prime word was living thing or nonliving living. The target word was the name of concrete thing classified as living (for example, a cat, dog, or goldfish, and so on) or nonliving (for example, a pencil, desk, spoon, and so on). The target word was followed the prime word and the subject judged whether it was a living thing or nonliving thing. In this research, target words were based on the expressive vocabulary of younger children edited by National Institute for Japanese Language and Linguistics. Therefore, we can reasonably speculate about and discuss the development of semantic understanding of words in children of elementary school age.

The above results were shown in the figure (Figure 5). The most characteristic point was the different wave distribution and wave pattern among different age groups in each sensory modality. As for the distribution, N400 induced by auditory modality extends from frontal to parietal distribution in younger children while in adults it was limited to frontal distribution. We can speculate that in younger children group need a lot of energy from the broad area of brain to process phonetic and semantic processing (Figure 5(a)). As for the wave pattern (Figure 5(d)), it is monophasic in younger children but it is biphasic in the older children group, which is similar to that of the adult group. Moreover, the latency was almost the same as in older children and the adults. Thus semantic processing through phonetic route should be matured by the age of 10–14 years.

Contrary to the auditory modality, the wave form of visual N400 (Figure 5(b) and 5(e)) changed from biphasic in the younger children group to monophasic in the older children group. The second peak of negative deflection in younger children group can be thought to reflect the process, whether the word is congruent or incongruent to the target word. The peak latency of the second peak of younger age group was almost the same as the auditory stimulus-induced single peak latency. This finding suggests that the processing time course after recognition of semantic categories of words in the younger age group was almost the same between auditory modality and in visual modality. However, the simultaneous presentation of auditory and visual stimulus (Figure 5(c) and 5(f)) significantly shortened the peak latency of N400 (450 ms at Fz) compared to that with the single modality. Moreover, the response time in the bimodal condition also was shorter than that with single modality. Therefore, in younger age group, double-stimulus presentation facilitates the semantic processing of words. In the visual modality, the older age group and the adult group showed almost the same wave patterns and the same latencies as each other. This means that visual modality also develops after 10 years of age for the semantic processing. Moreover, the older age group showed the same wave patterns of visual and bimodal wave pattern. Thus in the older age group, visual dominancy is speculated than auditory modality in semantic processing. Robinson and Sloutsky (2004) and Napolitano and Sloutsky (2004) reported that infants under 4 years of age to whom simultaneous auditory and visual stimuli were presented, auditory route was dominant; vice versa, in the adults, visual route dominancy was shown. Thus, in the development of language acquisition, there seems to be a time of transient auditory dominant age.

Figure 5 Developmental change of N400 in three modalities. Black line is the grand average pattern of the younger children group ($n = 18$) at Fz. Blue line is the grand average pattern of the elder children group at Fz. Red line is the grand average pattern of the adult group at Fz. (a) and (d) Auditory modality, Younger children group showed monophasic pattern (↓). Elder children group showed biphasic pattern (▼). Adult children group showed low amplitude pattern (●). (b) and (e) Visual modality. Younger children group showed biphasic pattern (↓), Elder children group (▼) and adult group (●) showed almost monophasic pattern. (c) and (f) Auditory–visual modality. The wave shape of younger children (↓) is similar to that of the auditory modality. The wave shapes of the elder children group (▼) and adult group (●) are similar to those of the visual modality. Developmental changes of N400 event-related potential of a semantic category decision task and modality specific findings in patients with developmental dyslexia. No to Hattatsu 38, 431–438.

Summary

In this article, the neurophysiological markers of language development were described explaining the developmental change of MMN, P300, and N400. These parameters can be compared with the abnormal or deviated development of language.

Abstract

In this article, we present an overview of the current state of the art in neuroprosthetics, also known as brain–computer interfaces or brain–machine interfaces. First, we describe afferent neuroprosthetics, which are designed to convey sensory input through stimulation of neuronal populations that are implicated in perception. We then describe efferent interfaces that consist of using neuronal signals to control extra-corporeal devices.

Overview

Neuroprosthetics are devices that interface with the central nervous system (CNS) or the peripheral nervous system (PNS). While neuroprosthetics were first devised in the 1960s, recent technological advances have engendered important developments in this field, not only for neurorehabilitation, but also for gaming, virtual reality, and decision making. Neuroprosthetics can be classified into two main categories: afferent neuroprosthetics that write information into the brain, usually to provide sensory input and efferent neuroprosthetics that read information out of the brain to control an external device. These two categories can be further broken down into several subcategories that are usually defined by the site of stimulation for input brain–computer interface (BCI) and the type of response/command used for control in the case of output BCI.

Afferent Neuroprosthetics or Input BCI

Afferent neuroprosthetics consist of conveying sensory information by stimulating neuronal populations in the PNS or CNS. The oldest and most successful afferent neuroprosthesis to date is the cochlear implant (CI). Since the development of the CI, however, afferent neuroprostheses have expanded into other sensory modalities, and have recently begun to enter the cognitive domain as well.

Sensory Neuroprostheses

Auditory Neuroprostheses

Cochlear Implant

Children and adults with severe sensorineural hearing loss who cannot be helped by hearing aids are good candidates for CIs, as long as the auditory nerve is not damaged (**Figure 1**). Perceptive or sensorineural hearing loss is due to damage or loss of hair cells, which are the mechanoreceptors that mediate hearing, or damage to the cochlea (the structure in which these hair cells reside), and constitute a distinct condition from conductive hearing impairment loss, which affects the middle ear. Successful implementation of a CI depends on the age at onset, duration of deafness, the age at implantation, the etiology, and the implant model (NIH, 1995). Another important factor is whether the onset of hearing loss occurred before or after the development of a language. Indeed, while postlingually deaf adults experience an improvement in the perception of speech through their CI, prelingually deaf adults typically do not experience such a benefit. Nonetheless, noisy environments impair the ability of all CI patients to perceive speech, listen to music, or talk on the phone (Peterson et al., 2010). There is no age limit for a CI, but implantation before the age of 2 years tends to reduce the negative outcomes of auditory loss and allows for a more efficient acquisition of speech and language (NIH, 1995).

A CI comprises an internal component (the receiver), which consists of a module, placed beneath the skin, which contains a receiving antenna and an array of 8–22 electrodes. The electrode array is placed in the inner ear (cochlea) and stimulates the auditory nerve directly. The external part of the CI consists of a microphone that picks up surrounding sounds, a chip to process the information from the microphone, and a transmitter that sends signals to the receiver.

The surgery is performed under general anesthesia and typically lasts between 3 and 4 h. The patient lies supine with the head turned to the side. An incision is made behind the ear to allow the surgeon access to the layers of tissue between the

Figure 1 Location of cochlear implants (light orange) and brainstem implants (blue).

skin and the bone. A small cavity is drilled into the mastoid (the bone behind the ear) and the receiver is inserted into it. Another cavity is then drilled to access the inner ear and the auditory nerve, where the array of electrodes, shaped like a spiral to match the cochlea, is then inserted. About 3 weeks after the operation, the external component is installed and the device is calibrated. Calibration sessions consist of characterizing both perceptual thresholds and pain/discomfort levels. Then, different processing strategies are tested to determine which is best suited to the CI patient.

While single-channel CIs had been previously implanted, the first multichannel CI, known as the bionic ear, was implanted on 1 August 1978 by Professor Graeme Clark and his team at the University of Melbourne in Australia. The ten-channel implant recipient was Rod Saunders, a 48-year-old man who lost his hearing 18 months before the operation following an accident that damaged his cochlea. This implant led to several important discoveries about sound and speech processing (Clark, 2003).

Generally, the more electrodes or channels in a CI, the clearer is the perceived sound. While a single-channel implant can provide some conscious experience of sound, at least 6–8 channels are required for speech recognition. The number of implanted electrodes depends on the number of remaining hair cells in the cochlea. Commercial CIs have up to 22 electrodes. As might be expected, given the relatively small number of channels, CI-elicited sounds are far from natural.

Auditory Brainstem Implant

Patients who cannot benefit from a CI due to the absence of or damage to the auditory nerve can potentially benefit from auditory brainstem implants (ABIs), which bypass the auditory nerve and stimulate the brain directly. In most cases, patients suffer from neurofibromatosis type II (NF2), an inherited disease that requires the extraction of a nonbenign tumor in the vestibulocochlear nerve (cranial nerve VII), and thus of the auditory nerve itself. The design principle is similar to that of CIs, except that the electrode array is implanted in the cochlear nucleus in the brainstem (Rauschecker and Shannon, 2002).

The first ABI was implanted in an adult at the House Ear Institute, CA, in 1979 and consisted of two electrodes that stimulated the auditory brainstem. To date, about 900 adults worldwide have received an ABI. The Food and Drug Administration (FDA) approved clinical trials on children in January of 2013 and 3-year-old Grayson Clamp became the first child in the United States to receive the ABI in May of that year. The outcomes after the implantation are usually positive, as the patient is able to hear surrounding sounds and process speech during face-to-face communication. However, ABIs never reach the speech recognition level obtained with CIs for patients with NF2. Current ABIs consist of 10–12 electrodes that deliver electrical pulses to the surface of the cochlear nucleus. Colletti's team at the University of Verona developed an ABI with 8–10 penetrating electrodes (PABI) that provides better pitch sensations (Colletti et al., 2004; http://www.sciencedirect.com/science/article/pii/S019459980500344X) with reduced currents, although it does not produce a greater improvement in speech recognition than do standard ABIs (Otto et al., 2008; http://www.ncbi.nlm.nih.gov/pubmed/18931643). The level of speech recognition achieved with ABIs is equivalent to that of the first single-channel CIs.

Individuals who are not afflicted with NF2 were originally not eligible for an ABI because of the surgical risks. Indeed, in NF2 patients, the ABI is implanted just after the tumor removal and therefore does not require an additional surgery. With that proscription lifted, Colletti et al. showed that ABI patients without tumors exhibit better speech recognition than do ABI patients with tumors. In fact, their speech recognition is comparable to that of multichannel CI recipients. Importantly, as the surgical procedures, electrodes, and location are the same for ABI patients with and without tumor, it is likely that the removal of the NF2 tumor damages neural tissue that is essential to speech processing (Shannon, 2010). For children, the critical age for an ABI is the same as that for a CI.

Auditory Midbrain Implant

The fact that NF2 ABI patients' speech recognition does not improve significantly compared to that of non-NF2 ABI recipients suggests that the cochlear nucleus may be damaged by the tumor itself or during its removal. The inferior colliculus, an auditory structure in the midbrain, offers an alternative site of stimulation for NF2 patients (Lim et al., 2008, 2009). Although the results are encouraging, this technique is very recent, as less than 10 patients had been implanted with an AMI to date.

Visual Neuroprostheses

In contrast to their auditory counterparts, no visual prostheses are routinely used in the clinic. However, recent technological developments have opened new possibilities and some visual prostheses have been FDA and CE approved. To date, there are basically three main sites for interfacing with the visual system: the retina, the optic nerve, and the visual cortex. As is the case with CIs, an internal unit stimulates the cells after receiving the sensory information (in this case visual) from an external unit (**Figure 2**).

Retinal Implants

Retinal implants, whose scope is limited to retinal degradation or retinitis pigmentosa, are placed either on (epiretinal implant) or behind (subretinal implant) the retina, or above the vascular choroid (suprachoroidal implant).

1. Epiretinal implants

The external unit includes a miniature camera, an integrated circuit for signal processing, and a wireless connection

Figure 2 Implantation sites for epiretinal (blue), subretinal (red), optic nerve (green), and visual cortex (purple).

(radio frequency or infrared transmission), all mounted on a pair of glasses worn by the patient. The camera captures the images that are then processed by the integrated unit, which in turn sends stimulation commands to the internal implant. The implant consists of a receiver and an array of electrodes made that is mounted on a flexible silicon printed circuit and is attached to the inner layer of the retina. The necessary information and energy are received and sent to the electrodes that deliver electrical pulses to the retinal ganglion cells. Electrical stimulation of the retina typically results in the elicitation of phosphenes, spatially localized sensations of light. Several clinical trials of epiretinal implants have been successfully carried out on patients with retinitis pigmentosa (Humayun et al., 1996; Chader et al., 2009), and the first FDA-approved implant, ARGUS II, afforded patients spatial navigation and simple motor tasks (Ahuja et al., 2011).

2. Subretinal implants

In subretinal implants, an array of micro-photodiodes is implanted in the outer layer of the retina and replaces the damaged photoreceptors by capturing the light entering the eye, no external camera is required. Activation of individual photodiodes results in the delivery of electrical pulses to the other layers of the retina (biopolar and ganglion cells). However, since micro-photodiodes are situated in the outer layer of the retina, the path of light is sometimes impeded, so these types of implants require an additional energy source to compensate for this issue. While subretinal implants are not commercially available, patients in clinical trials have reported the perception of phosphenes (Benav et al., 2010; Zrenner et al., 2010). Some problems related to implant corrosion have led to explantation in some patients (Stingl et al., 2013) and need to be addressed before these devices become more widespread.

3. Suprachoroidal implant

In suprachoroidal–transretinal stimulation, an implant is placed in the suprachoroidal space within the sclera (white of the eye). While the implant is not in contact with the retina, this technique has the advantage over its epi- or subretinal counterparts in that the surgery is easier and safer for patients and results in more stable electrodes positioning (Fujikado et al., 2011). While implants in animals and a few human subjects have been promising, this approach is still experimental, as more efficient surgical techniques are under investigation. Moreover, the spatial resolution is still unknown and is expected to be lower than that of retinal implants.

4. Summary

The advantage of subretinal implants over epiretinal ones is that the former interface with the nervous system at an earlier stage, that is, when the light is converted into electrical impulses, which allows the image to move with the eyes in a natural way. Furthermore, the surgical procedure involved for subretinal implants is simple, as the implant is held in place by the space between the outer layer and the retinal pigment cells. In contrast, tacks are necessary to attach the epiretinal implant to the tissue. One of the major drawbacks of subretinal implants is that the light has to cross several layers to reach the micro-photodiodes. The quantity of light that reaches the implant affects the resolution, and often an external power source is added to the external module. Suprachoroidal–transretinal stimulation may offer more stable electrode attachment than do retinal implants and thus be less susceptible to variability in thresholds and to cause damage to retinal neurons.

Both retinal implants stimulate the first layer of cells in the retina if these are intact and functional. Both the implantation procedures are more straightforward than those required for optic nerve or cortical stimulation. However, retinal implants cannot be used in diseases that affect ganglion cells, such as glaucoma. To date, only one epiretinal implant, the Argus II, has been approved by the FDA and in Europe. A subretinal implant, the 'Retina' implant, manufactured in Germany, is also available commercially in CE. The surgical procedure for the suprachoroidal implant is the least risky, as the electrodes are inserted in the space between the sclera and the choroid and, therefore, are not likely to damage the retina. However, as the stimulation is applied to the choroid layers rather than to the retina itself, the resolution is potentially lower.

Optic Nerve Stimulation

An interface with the optic nerve was developed by Veraart et al. (2003) and successfully implemented in only one patient (Brelén et al., 2006). Indeed, the organization and structure of the optic nerve fibers limits the feasibility of optic nerve stimulation: removing the membrane that protects the 1 million optic nerve fibers of optic nerve that runs the risk of damaging the nervous tissue, which makes selective stimulation of optic fibers challenging. However, if deemed feasible, this method would offer the advantage of being applicable to any disease affecting the eye.

Visual Cortex Stimulation

1. History and overview

Foester first reported that stimulating the surface of the occipital cortex (epicortical stimulation) elicited the perception of spots of light called phosphenes. This discovery led to what can be considered the first cortical implant in 1968 (Brindley and Lewin, 1968), which consisted of an array of 80 surface electrodes implanted in the visual cortex of a 52-year-old patient with glaucoma (Weiland and Humayun, 2006). They estimated that 50 electrodes would be required to restore enough vision to read one letter at a time, and at least 600 electrodes to achieve normal reading.

Surface stimulation of visual cortex required high levels of electrical current to elicit visual percepts and led to very large phosphenes, thereby limiting the spatial resolution of the resulting signal. In the 1980s, invasive technology was developed that allowed for intracortical stimulation that consists of delivering electrical stimulation through electrodes that penetrate the cortical tissue. A commonly used intracortical interface is the Utah Electrode Array, which consists of a 10×10 grid of electrodes spanning 4.2×4.2 mm. Individual electrodes are 1- or 1.5-mm long and are separated from each other by 400 μm (Normann et al., 1999).
